Postpartum Depression. Despite the absence of endocrine abnormalities in this disorder, women with PPD show an enduring abnormal mood response to reproductive hormones. A previous study demonstrated that exposure of euthymic women with a history of PPD to high doses of estradiol and progesterone followed by abrupt hormone withdrawal produced depression not seen in women lacking a history of PPD. This suggested that PPD occurred in a subgroup of women who were susceptible to reproductive hormone–linked affective disturbances. In parallel, supplemental reproductive steroids have been administered during the immediate postpartum in an attempt to prevent or treat postpartum affective disorders. An open trial in women at risk for puerperal psychosis demonstrated that high-dose estrogen treatment resulted in a lower-than-expected 1-year recurrence rate (9% compared with an expected 35% to 60% without prophylaxis). Varying doses of estrogen (Premarin ranging in dose from 0.625 to 10 mg/day or intravenous [IV] estradiol 25 mg q8h) were administered immediately postpartum and then tapered over 4 weeks. It was suggested that estrogen administration could attenuate the rapid puerperal drop in estradiol levels, thereby reducing the negative impact of the postpartum "estrogen withdrawal state" on mood. In a follow-up study, investigators tested the suggestion that estradiol withdrawal caused PPD in a double-blind, placebo-controlled study of estradiol in 61 women who developed major depression within 3 months of delivery. Eighty percent of the patients receiving estradiol (estrogen patch) experienced a significant reduction in depression severity after 3 months of treatment, compared with 31% of the placebo-treated group. Decreased mood symptoms on ET were observed in women regardless of concurrent antidepressant use, and estrogen's antidepressant effects were rapid and observed after 2 to 3 weeks of treatment. A similar rapid response to estradiol was also recently reported in an open-label trial of sublingual estradiol, similar to the timing of the response to estradiol in perimenopausal depression. Double-blind, placebo-controlled trials of estradiol in the treatment of PPD are ongoing and will help define the role of estradiol monotherapy in PPD.

An intriguing animal model suggested underlying mechanisms for the critical observations in PPD: the triggering of symptoms during a specific reproductive context (the puerperium) in a select genetic context conferring differential sensitivity to hormonal changes. In this model, a partial knockout of the delta-subunit of the $GABA_A$ receptor resulted in behavioral changes (increased sensitivity to stress and depressive-like behavior) that appeared only after the dams delivered. The extrasynaptic effects of allopregnanolone are mediated through the delta-subunit–containing $GABA_A$ receptors, and administration of allopregnanolone prevents adverse behavioral changes. These data were foundational in conducting a trial of a modified form of allopregnanolone, brexanolone, in PPD. The efficacy of a 60-hour infusion of brexanolone IV was demonstrated in a multicenter trial, with therapeutic separation from placebo seen by 24 hours and persisting for at least 30 days. These findings resulted in rapid FDA approval of the first treatment specifically for PPD. As oral forms of progesterone-derived neurosteroids are being developed, this class of compounds may represent a significant, practical addition to our therapeutic armamentarium.

Estradiol and SERMS in Acute Psychosis

Animal studies suggest potential neuromodulatory interactions between the dopaminergic system and estradiol signaling pathways. Estradiol priming has been reported to increase dopamine synthesis, affect dopamine turnover, and alter both pre- and postsynaptic D_1 and $D_{2/3}$ receptor binding affinity. Indeed, estradiol was reported to change $D_{2/3}$ receptors from high- to low-affinity states.

Since dysregulated dopamine action serves a pivotal role in the pathophysiology of psychosis, the supplementation of estradiol could potentially impact central dopaminergic function and mitigate the psychotic state. Interestingly, several trials have demonstrated therapeutic effects of physiologic doses of estradiol (i.e., 100 mcg per day) or SERMs in acute psychoses (double-blinded). In many of these studies, clinical effects have been evident within 2 weeks of administering the first dose of estradiol. However, the role of dopaminergic system dysfunction in the treatment response to ET or SERMS has not been fully characterized.

Androgen Administration in Midlife Depression

Several investigations have suggested that the change in mood, cognition, and libido during perimenopause/postmenopause may reflect deficiencies in androgens rather than (or in addition to) estrogens. Indeed, midlife in both men and women is characterized by a steady decline in the production of androgens such as dehydroepiandrosterone (DHEA) and androstenedione, which are mostly of adrenal origin yet contribute up to 50% of circulating androgen levels (testosterone, dihydrotestosterone) in women. Nonetheless, the definition of low testosterone levels is severely compromised by the current inability to accurately measure peripheral levels of testosterone in women or hypogonadal men (similar to the methodologic obstacles for measuring low estradiol levels). These assay limitations preclude the clear identification of men or women in whom androgen secretion is deficient (and in whom testosterone therapy would be indicated). Indeed, recent clinical practice guidelines recommend against making a diagnosis of androgen deficiency in women because of both the lack of a well-defined syndrome and the unavailability of reliable data correlating peripheral androgen levels with specific signs or symptoms. Moreover, the practice guidelines discourage the prescription of either DHEA or testosterone therapies in women because there are only limited data supporting therapeutic benefits for the targeted symptoms, and there are no long-term studies examining the risks of androgen therapy. In healthy men, there is considerable variability in the blood levels of testosterone below which symptoms develop, and the emergence of hypogonadal symptoms (e.g., decreased libido, fatigue, and depression) in aging men are frequently confounded by obesity and other comorbidities. Indeed, results from a recent hormone manipulation trial showed that the level of testosterone below which symptoms emerge both varies across men and is considerably below levels normally reported to accompany hypogonadism in men. Thus, testosterone therapy in older men also should be employed cautiously, and the initial management of age-related hypogonadal symptoms should focus on the achievement of a more normal body mass index (BMI) and management of comorbidities. That said, androgen therapy has anecdotally been reported to benefit both mood and sexual function/libido in males who are clinically hypogonadal. Further, several investigators and a recent meta-analysis have shown that androgens improve a variety of elements of sexual function (desire, arousal, fantasies) when administered as sole treatment (ovariectomized women) or in combination with estradiol (postmenopausal women). Medical literature dating back to the isolation of testosterone in 1935 is replete with reports of the antidepressant efficacy of testosterone, androgen/anabolic steroids, and adrenal (and ovarian) androgens like DHEA. While most of these reports were uncontrolled, one study in ovariectomized women again demonstrated the superiority of testosterone to placebo in the mitigation of depressive symptoms. If androgens can improve mood, are they effective only in the context of clinically demonstrable androgen deficiency (which, as noted above, is difficult to reliably determine)? Further, even if shown to “improve well-being” (as was DHEA in older men and women), is androgen treatment effective in clinically significant affective disorders? Indeed, a recent meta-analysis concluded that in women with normal adrenal function, the administration of DHEA is not indicated for complaints of either depressed mood or decreased sexual interest or arousal. This meta-analysis, however, does not answer the question of DHEA’s efficacy in clinically significant depression since the majority of the reviewed studies were not sufficiently powered to evaluate DHEA’s effects on depression. As should, by now, be clear, this, like other forms of HT, has attendant nonuniform benefits and risks. DHEA, for example, may improve bone mineral density with chronic administration, thus helping to prevent age-related osteopenia (although, with the exception of small improvements in lumbar spine density in women, a recent meta-analysis found little evidence that DHEA had significant effects on bone density in women). It has been suggested, however, that DHEA administration, while not increasing total plasma testosterone levels in men, might be concentrated in the prostate, where local conversion to testosterone could accelerate the growth of androgen-dependent tumors.

FUTURE DIRECTIONS

There is little question that reproductive hormones can regulate mood and that manipulations of reproductive hormones can, in some instances, dramatically alter the course and expression of affective illness. It is equally clear that these hormonal effects are not universal and appear in subgroups of individuals who appear differentially sensitive to these central actions of reproductive steroids. A major task for the future will be to identify the mediators of this differential sensitivity. Identification of the genetic or other predictors of vulnerability to reproductive endocrine-related mood disorders would assist in the identification of those who would respond to reproductive therapies and those who might be at risk for adverse effects. Indeed, the main constraint on the effective incorporation of reproductive hormonal modulators into the psychotherapeutic armamentarium as primary psychotropic agents or adjunctive therapies (e.g., in those who experience incomplete responses to other psychotropic agents) is the inability to predict the likelihood of adverse medical outcomes (e.g., breast cancer). In addition, it is now clear that direct assays of sex steroids in populations with low levels of sex steroids (i.e., postmenopausal women, older adult men, and young children) are no longer acceptable evidence to confirm endocrine “deficiency” states, although even if accurate, single plasma hormone levels will not detect the pharmacodynamic differences across individuals that may result in marked phenotypic variation. The specificity and complexity of the actions of individual hormonal agents preclude generalization about the likely therapeutic or adverse outcome of exposure to a given hormone. Slight structural differences between the hormonal agents available in a given class can translate into dramatic differences in cellular and physiologic effects (and hence efficacy and risk), as can the timing of administration of these agents (i.e., their continuous or discontinuous administration). While generating current uncertainty, the specificity of actions of individual hormonal preparations, steroidogenic enzyme inhibitors, and steroid receptor antagonists creates an extraordinary opportunity for the development of tissue-specific pharmacologic agents. The SERMs already available, for example, not only possess the beneficial effects of estradiol in some tissues (e.g., bone) but additionally block the potentially harmful effects of estradiol in other tissues (e.g., breast). Current knowledge, then, of tissue-specific coregulators will increasingly permit the design of reproductive agents that select and restrict the tissues affected and the actions elicited. In this fashion, the goal of psychopharmacologic precision will be greatly advanced.

33.17c Pharmacologic Treatment of Sexual Dysfunction

CARIDAD PONCE MARTINEZ, M.D., SARIA EL HADDAD, M.D., AND ANITA H. CLAYTON, M.D.

Satisfactory sexual functioning is an important part of the human experience and contributes to the overall quality of life. According to the World Health Organization, sexual health is "a state of physical, emotional, mental and social well-being in relation to sexuality; it is not merely the absence of disease, dysfunction, or infirmity." Sexual dysfunction is a syndrome comprised of pathologies that can affect women and men across several phases of the sexual response cycle, desire, arousal, and orgasm, plus sexual pain. It is frequently multifactorial, with biologic, psychological, sociocultural, and interpersonal/relational factors. There are important sex differences in the neurobiology, etiology, and comorbid sexual/medical/psychiatric conditions, including associated medications, that highlight the need for different strategies in the evaluation and management of sexual dysfunction.

The DSM-5 categorizes sexual dysfunctions into gender-specific disorders of impaired desire or excitation (male hypoactive sexual desire disorder [HSDD], erectile disorder [ED], female sexual interest/arousal disorder [FSI/AD]), disorders involving orgasm (female orgasmic disorder [FOD], delayed ejaculation, premature or early ejaculation [PE]), disorders of pain/penetration (genitopelvic pain/penetration disorder—female only), and others (substance/medication-induced sexual dysfunction, other-specified sexual dysfunction, and unspecified sexual dysfunction). The diagnosis of FSI/AD resulted from an integration of HSDD and female sexual arousal disorder (FSAD) in the previous editions of the DSM. Clinical treatment and research have focused on desire and arousal separately, as essentially all studies/publications utilized the DSM-IV diagnoses. As such, in this chapter, we will focus on pharmacologic treatment of HSDD and FSAD rather than the combined FSI/AD, FOD, ED, and PE. The 10th revision of the ***International Statistical Classification of Diseases and Related Health Problems*** (ICD-10) codes corresponding disorders as gender neutral and includes lack or loss of sexual desire, failure of genital response, orgasmic dysfunction, and PE. The ICD-11 has a separate chapter for sexual health, which includes parallel sexual dysfunctions for women and men. Table 33.17c–1 displays the diagnoses across DSM and ICD versions for comparison.

Although each of these disorders has its specified diagnostic criteria, it is important to note that they frequently coexist, highlighting the importance of a full assessment once sexual dysfunction is identified. Furthermore, the DSM-5 requires symptoms to be present for at least 6 months for a diagnosis of a disorder. Lifelong sexual dysfunctions are present following initiation of sexual activity, while acquired sexual disorders occur after a period of normal sexual function per the individual. Distress about sexual dysfunction is a required criterion for diagnosis. The disorder can be situational in that it is specific to certain types of stimulation, situations, or partners, or it can be generalized. The severity of the disorder can be mild, moderate, or severe, depending on the level of distress the symptoms cause in the individual.

Table 33.17c–1.
Classification of Sexual Dysfunctions in Recent Versions of DSM and ICD

		DSM-IV-TR	ICD-10	DSM-5	ICD-11
Female	Desire	Hypoactive sexual desire disorder	F52.0 Lack or loss of sexual desire	Female sexual interest/arousal disorder	HA00 Hypoactive sexual desire dysfunction
	Excitation	Female sexual arousal disorder	F52.2 Failure of genital response		HA01.0 Female sexual arousal dysfunction
	Orgasm	Female orgasmic disorder	F52.3 Orgasmic dysfunction	Female sexual interest/arousal disorder	HA02.0 Anorgasmia
	Pain/penetration	Dyspareunia	N94.1 Dyspareunia	Genitopelvic pain/penetration disorder	GA12 Dyspareunia
		Vaginismus	N94.2 Vaginismus		HA20 Sexual pain-penetration disorder
Male	Desire	Hypoactive sexual desire disorder	F52.0 Lack or loss of sexual desire	Male hypoactive sexual desire disorder	HA00 Hypoactive sexual desire dysfunction
	Excitation	Erectile disorder	F52.2 Failure of genital response	Erectile disorder	HA01.1 Male erectile dysfunction
	Orgasm	Premature ejaculation	F52.4 Premature ejaculation	Premature ejaculation	HA03.0 Male early ejaculation
		Delayed ejaculation	F52.3 Orgasmic dysfunction	Delayed ejaculation	HA03.1 Male delayed ejaculation
Both		Substance/medication-induced sexual dysfunction		Substance/medication-induced sexual dysfunction	

Establishing the prevalence of sexual dysfunction (SD) has been complicated by variations in definitions (sexual complaints, SDs, sexual dysfunctions), variations in how SD is assessed (self-report vs. validated/nonvalidated measures), variations in populations studied, the inclusion of distress, cultural effects, and co-occurring sexual dysfunctions, among other factors. Men more commonly seek evaluation for sexual dysfunction. However, women experience a high prevalence of sexual dysfunction.

The National Health and Social Life Survey (NHSLS) was a study of sexual behavior in U.S. adults aged 18 to 59 years. In 1992, 1,749 women and 1,410 men were randomly selected; the evaluation assessed the risk of experiencing SD as well as associated negative outcomes but did not evaluate distress. SD was more prevalent in women (43%) than men (31%). The most common problems in women were desire (32%), orgasm (26%), and lubrication (21%). In men, PE was the most common complaint (30%), compared to erectile dysfunction (10%) and low desire (14%). SD was associated with demographic characteristics, including age and educational attainment. Sexual concerns were more likely among men and women with poor physical and emotional health and were highly associated with negative experiences in sexual relationships and overall well-being.

ED is the most common type of sexual dysfunction in men, with an estimated prevalence in the U.S. male population aged 20 years or older of 18.4%, equivalent to more than 18 million men. In the Massachusetts Male Aging Study, which surveyed approximately 1,700 men longitudinally, the combined prevalence of ED was 52%, with 39% in 40-year-old men and 67% in men aged 70 years or older. After adjusting for age, the strongest correlates for ED were markers of cardiovascular disease—hypertension, diabetes, and heart disease.

HSDD is the most common type of sexual dysfunction in women, with prevalence ranging between 17% to 50% depending on the population studied, methodology, and definition. In the Prevalence of Female Sexual Problems Associated with Distress and Determinants of Treatment Seeking (PRESIDE) study, which included 31,581 U.S. female respondents from 50,002 households (63% response rate) between the ages of 18 to 102 years, low desire was the most common sexual problem (38.7% of participants); low arousal and orgasm difficulties had prevalence rates of 26.1% and 20.5%, respectively. Low desire associated with distress (HSDD) was present in 10% of women and was more common than personally distressing problems with arousal or orgasm (5.4% and 4.7%, respectively). Any sexual problem associated with personal distress occurred in about 12% of women. Depression was positively associated with problems with desire and orgasm.

In men, increased age is associated with a higher frequency of erection problems and decreased sexual desire. In women, the prevalence of sexual problems tends to peak in the middle years, then decrease with increasing age, except for changes associated with menopause (e.g., trouble lubricating); however, this has not been a consistent finding across studies. Poor health is associated with increased risk for all categories of sexual dysfunction in men, whereas in women, it is only associated with increased sexual pain.

PATHOPHYSIOLOGY

Normal sexual function involves psychological, social, and biologic processes. Biologic or organic factors that include medical conditions, surgical procedures, medications, recreational substances, and lifestyle factors can negatively impact sexual function and lead to sexual dysfunction. Psychosocial factors such as depression, anxiety, traumatic experiences, relationship problems, prior experiences, moral prohibitions, and psychosocial stressors can also play an important role. Many cases of SD have both biologic and psychogenic features. Even in cases of clear organic etiology like perineal trauma, impaired sexual function can result in psychological consequences such as low self-esteem, low self-confidence, and even anxiety or depressed affect, which can further exacerbate the dysfunction. Involvement of sexual partners during evaluation and treatment is important in education about the diagnosis and in examining patient and partner expectations for treatment outcomes. Studies have identified a bidirectional association in sexual dysfunction between partners, with a threefold increase in male SD when the female partner had SD and a significant increase in female SD and infrequency of sex associated with male SD.

The neurobiology of sexual functioning is mediated by neurotransmitters, sex steroids, and other hormones with actions in the central nervous system and peripherally in the urogenital organs. Sexual excitation involves dopamine, norepinephrine, nitric oxide, oxytocin, vasopressin, and melanocortins. Inhibition involves serotonin, prolactin, endocannabinoids, and opioids. Normal levels of sex steroids such as testosterone and estrogen increase the sensitivity of an individual toward sexual stimuli centrally and peripherally.

In generalized HSDD, increased inhibition and/or decreased excitation appear to mediate low desire. In women, sex hormones play a crucial role in all phases of the sexual response cycle. Estradiol affects sexual desire and genital structures. In hypoestrogenic states, whether natural (e.g., perimenopause, postmenopause, and postpartum) or acquired (e.g., hormonal chemotherapies, surgical menopause), the resulting physiologic changes may affect sexual functioning due to the peripheral effects of atrophy of urogenital tissues, inadequate vaginal lubrication, or reduced capacity for arousal and orgasm due to reduced vaginal blood flow. In addition, hormonal contraceptives containing estrogen may increase sex hormone–binding globulin (SHBG) which binds testosterone, lowers free or bioavailable testosterone, and may impact sexual desire and arousal. In females, despite the importance of testosterone in normal sexual function, testosterone serum levels do not correlate with sexual desire, nor do they reflect intracrine sex hormone production. This is likely because testosterone levels in females are much lower than in men, and current assays do not accurately measure these low free and total testosterone levels.

In addition to the neuroendocrine factors described above, medications such as antidepressants, antiandrogens, and oral contraceptives can contribute to female sexual dysfunction. The most common psychological factors affecting female sexual function are depression, anxiety, distraction, negative body image, and trauma. In medically healthy women, problems with sexual arousal are often the result of insufficient sexual stimulation rather than organic causes. Vascular disease, associated with diabetes mellitus (DM) and atherosclerosis, as well as many of its treatments, can cause arousal problems in women by inhibiting smooth muscle relaxation and vasocongestion, necessary for the engorgement of the clitoris and vagina, and resulting lubrication. There is conflicting data, however, regarding the relationship between metabolic syndrome and HSDD.

In general terms, ED can be classified as psychogenic, organic, or mixed. Psychogenic factors such as performance anxiety and others mentioned previously can negatively impact erectile function. This type of ED tends to occur on a situational basis, has a sudden onset, and concurrently, men can experience normal erections with masturbation, at night or upon awakening. Organic processes can be vascular (e.g., arterial insufficiency, venous leakage), neurologic, endocrine (e.g., hypogonadism, hyperprolactinemia), substance induced, or due to a systemic illness. In these cases, ED tends to be more insidious in its onset, and erections are deficient in most contexts (masturbation, nocturnal).

Healthy vascular and neurologic functions are necessary for an erection to occur. There is a neurologically mediated increase in penile arterial inflow. Nitric oxide is released from the endothelium and parasympathetic nerve terminals, allowing relaxation of the cavernosal smooth muscle, vasocongestion, and engorgement of penile tissue, resulting in an erection. A vasculogenic etiology is the most common among organic etiologies of ED. Current evidence suggests a strong correlation between cardiovascular disease and ED, with a common pathophysiologic basis of endothelial dysfunction, inflammation, and low testosterone. ED is also associated with coronary heart disease, stroke, and all-cause mortality. The presence of vasculogenic ED in young men can be a particularly early indicator of future cardiovascular disease, and these patients should receive an appropriate cardiovascular workup for risk stratification.

Risk factors for ED can be examined in accordance with etiology. Some neurologic disorders (e.g., multiple sclerosis, stroke, temporal lobe epilepsy, Parkinson disease, Alzheimer disease, spinal cord injury) are associated with ED, and the risk of nerve injury leading to ED is very high in patients undergoing radical pelvic surgery. Endocrine risk factors include hypogonadism, hyperprolactinemia, and hypothyroidism. Some risk factors for vasculogenic ED are atherosclerosis, hypertension, hyperlipidemia, obesity, smoking, DM, and pelvic irradiation. Among men with DM, 50% to 75% develop ED; the prevalence of ED in diabetics is three times that seen in nondiabetics. Lower urinary tract symptoms have also been linked to the development of ED. The most common medications that can cause or contribute to ED are antiandrogens, antihypertensives (thiazide diuretics, beta-blockers, calcium channel blockers), antiarrhythmics (e.g., digoxin), and many psychotropic drugs (tricyclic antidepressants, selective serotonin reuptake inhibitors [SSRIs], phenothiazines, and butyrophenones).

The use of recreational, illegal, or controlled substances may contribute to sexual dysfunction in both men and women, although the evidence for most substances is very limited, particularly in regard to women. Table 33.17c–2 summarizes some of these findings. An umbrella review of 98 meta-analyses sought to synthesize all of the available meta-analytic research on the risk factors, treatment, and prevalence of SD; substances evaluated included tobacco, alcohol, caffeine, cannabis, and opioids. A systematic review and meta-analysis including 8,829 men from 10 studies indicated that the use of opioids was significantly associated with an increased risk of ED (RR = 1.96, 95% confidence interval [CI] 1.66 to 2.32, $p < .001$), although the overall quality of evidence was rated as low due to observational study designs. This study included methadone, heroin, opium, and other opioids, but there remains limited knowledge on the effects of medications used in the treatment of opioid use disorder, buprenorphine and naltrexone. Heroin appears to raise testosterone-binding globulin levels and thus, reduce plasma levels of free testosterone; heroin and other opioids also affect the mesolimbic dopamine reward pathway, which may contribute to reduced reward with sex. Cocaine use may initially enhance sexual functioning by increasing desire, but prolonged use may affect desire and orgasm. Amphetamines are popularly considered potent aphrodisiacs, and methamphetamines are perceived to be sexual enhancers due to increased social confidence, sexual disinhibition, and a sense of physical energy. There is no scientific evidence linking it to direct action on specific receptors that can enhance sexuality.

Table 33.17c–2.
Effect of Recreational/Illegal Substances on Sexual Dysfunctions

	Effect on Sexual Function
Tobacco	↑ ED (linear dose-response association)
Alcohol	Moderate (***mode*** = ***1–3 drinks/day; mean*** = ***7–8 drinks/ week***): ↓ risk of ED High (***mode*** >***3 drinks/day; mean*** = ***23.1 drinks/week***): ↑ risk of ED
Cannabis	Inconclusive (Results likely due to intermittent vs. chronic daily use)
Opioids	↑ risk of ED (unclear if applicable to buprenorphine, naltrexone)
Cocaine	↑ desire initially Chronic daily use: ↓ desire, ↓ orgasm
Amphetamines	Perceived enhancement of sexual function (↑ confidence/enjoyment and ↓ inhibition) but no objective improvement Chronic use: ED, delayed ejaculation, delayed orgasm in women

ED, erectile disorder.

PE can occur due to organic causes (e.g., urologic or thyroid dysfunction) but is most often the result of a normal variation of ejaculatory performance or due to psychological/relationship problems. PE is present in about a third of patients complaining of ED. As a result, patients may often respond to psychoeducation, reassurance, or psychotherapy.

ASSESSMENT

Assessment of sexual dysfunction is best performed using a biopsychosocial approach and should include psychiatric history, medical and surgical history, sexual history, family history, and social history. Detailed substance abuse and medication histories can help identify substance-induced SD.

Screening questions in women need to include HSDD in reproductive-age women and pain/dyspareunia in peri- and postmenopausal women. When evaluating HSDD in women, contributing conditions such as vaginal atrophy, vaginitis, diabetes, and lactation need to be ruled out.

In men, questions include erectile dysfunction and PE. A brief screening tool can be used to look at every phase of the sexual response cycle in both men and women. The Decreased Sexual Desire Screener (DSDS) can be used for HSDD and the abridged version of the International Index of Erectile Function (IIEF-5) for ED.

In addition to the interview, an evaluation for ED includes a general physical examination with particular emphasis on the nervous, vascular, and genital systems. Diagnosis is based on clinical presentation, not laboratory values. Laboratory studies can be utilized to rule out endocrine causes and identify associated comorbid conditions. The International Society for Sexual Medicine recommends ordering tests to measure fasting glucose, hemoglobin A1c (HbA1c), lipids, and total testosterone levels.

TREATMENT

Prior to starting specific interventions, initial management should address modifiable risk factors for sexual dysfunction. These include minimizing medication side effects and addressing the use of illicit/recreational substances, including tobacco. Management of cardiovascular risk factors includes weight management, exercise, and the adoption of a Mediterranean diet. In men with obstructive sleep apnea (OSA), treatment with continuous positive airway pressure (CPAP) is associated with some improvement in sexual function. Finally, gastric bypass surgery can increase testosterone levels and therefore improve sexual function in men with morbid obesity.

Involvement of the sexual partner may be useful in order to explore psychosocial or relational issues and evaluate the benefit of psychotherapy.

Psychotherapy in the form of individual cognitive behavioral therapy and couples therapy is utilized, randomized, adequately controlled clinical trials on its efficacy are lacking.

Specific Interventions

Hypoactive Sexual Desire Disorder. There are two Food and Drug Administration (FDA)-approved agents for the treatment of acquired, generalized HSDD in premenopausal women, flibanserin and bremelanotide.

Flibanserin, approved in 2015, is a 5-HT1A agonist and a 5-HT2A antagonist, which in the prefrontal cortex causes a decrease in serotonin and an increase in norepinephrine and dopamine activity. Efficacy trials in pre- and postmenopausal women indicate that flibanserin can cause an increase in sexual desire and satisfying sexual events and reduce distress related to sexual desire.

Dosed at 100 mg nightly, flibanserin is generally well-tolerated with side effects including dizziness, sedation, and fatigue. Initially, the FDA required a Risk Evaluation and Mitigation Strategy (REMS) program with a boxed warning to avoid alcohol with flibanserin due to concerns for hypotension and syncope. Three postapproval compulsory studies demonstrated no clinically significant risk if the use of flibanserin was separated by at least 2 hours from alcohol consumption. As a result, the FDA removed the REMS.

The melanocortin-4 receptor modulates sexual arousal and behavior, as supported by evidence in studies of mice, rats, and primates. Bremelanotide, a novel melanocortin receptor agonist, approved in 2019, is available in an autoinjector for subcutaneous formulation to be administered 45 minutes prior to anticipated sexual activity. Dosing should be limited to once a day (effect lasts around 24 hours) and no more than eight times a month. The most common side effect is nausea. It can cause transient hypertension so avoid in those with hypertension or cardiovascular illness.

Off-label agents include bupropion and transdermal testosterone. Sustained-release bupropion in premenopausal women was shown to improve sexual arousal, orgasm completion, and sexual satisfaction. Transdermal testosterone administration was shown to have favorable outcomes in all domains of sexual function and reduction in personal distress in postmenopausal women.

Female Sexual Arousal Disorder. Mindfulness-based therapy has been studied for FSAD and was found to have a beneficial effect on sexual desire and sexual distress. The efficacy seemed to be more pronounced in women with a history of sexual trauma. Nevertheless, mindfulness-based cognitive therapy (MBCT) and other psychological interventions are the mainstays of treatment when pharmacologic treatment is ineffective or causes intolerable side effects.

Female Orgasmic Disorder. The approach to treating FOD is largely psychoeducational. A variety of approaches have been tested, with the most consistent support emerging for directed masturbation, sensate focus, and psychotherapy.

EROS is a medical device approved in 2000 that consists of a small vacuum pump applied over the clitoris to stimulate blood flow, aiding in sexual arousal and orgasm.

Adequate stimulation is required for orgasm; enhancing arousal with off-label drugs such as bupropion, bremelanotide, and Phosphodiesterase-5 inhibitors (PDE-5Is) may facilitate achieving orgasm and enhance the frequency, intensity, and duration of orgasm.

Erectile Disorder. Nitric oxide (NO) mediates tumescence by increasing the levels of cyclic guanosine monophosphate (cGMP), which in turn leads to smooth muscle relaxation in the corpus cavernosum, allowing for engorgement with blood, resulting in an erection. Dilatation of the penile arteries leads to a more prolonged erection.

Phosphodiesterase-5 (PDE-5) is an enzyme that catabolizes cGMP. PDE-5 Inhibitors (PDE-5Is) competitively inhibit the PDE-5 enzyme and increase intracavernosal cGMP, thereby leading to an increase in both the number and duration of erections in men with ED. PDE-5Is improve endothelial function and reduce apoptosis of vascular smooth muscle cells in the corpus cavernosum.

Adequate testosterone levels and sufficient psychological and environmental cues that lead to sexual arousal and stimulation are required for PDE-5Is to work.

An evaluation of the underlying cause of ED is necessary prior to the initiation of PDE-5I treatment. These agents are contraindicated in men treated with nitrates and are to be used cautiously in men treated with alpha-adrenergic blockers. Vardenafil is known to cause minor QT prolongation and is, therefore, contraindicated in patients taking type 1A and type 3 antiarrhythmics and patients with congenital prolonged QT syndrome.

Treatment response seems to be largely dependent on proper use and administration (Table 33.17c–3).

SILDENAFIL. A meta-analysis of 27 trials in 6,659 men with ED showed a marked difference in the percentage of successful sexual intercourse between sildenafil and placebo (57% vs. 21%, respectively).

Sildenafil was also found effective for the treatment of ED in the setting of various conditions, including DM, prostate cancer treatment, parkinsonism, and depression treated with SSRIs.

Sildenafil could also have psychological benefits in men with ED, as shown by improvement in the mean self-esteem subscale score of the Self-Esteem and Relationship (SEAR) questionnaire (a psychometric instrument specific to ED).

Sildenafil is also available in an orodispersible form that disintegrates within seconds of ingestion leading to quicker absorption. This formulation offers an added advantage in patients with dysphagia.

VARDENAFIL. Vardenafil shares a similar structure and pharmacokinetic profile with sildenafil. It is efficacious in ED secondary to DM and nerve-sparing prostatectomy. It is also available in an orally disintegrating form and may have a more rapid onset of action.

TADALAFIL. Tadalafil is structurally distinct from sildenafil and vardenafil. It has a longer half-life than other PDE-5Is, thereby allowing the user greater flexibility in participating in sexual activity. Low dose may be taken daily.

AVANAFIL. Avanafil is a new agent currently approved in the United States and Europe for the treatment of ED. It is more selective to PDE-5 and has a more rapid onset of action.

Adverse Effects and Precautions. Common side effects include flushing, headache, and dyspepsia.

Table 33.17c–3.
Comparison of PDE-5 Inhibitors

Medication	Onset of Action and Duration	Dosing
Sildenafil	Effective for as-needed treatment of organic, psychogenic, or mixed-type ED Taken 1 hour before sex and effective up to 4 hours	50–100 mg on an empty stomach Administration with a high-fat meal may delay absorption 25 mg if coadministered with a strong CYP3A4 inhibitor or an alpha-1 blocker and in patients with renal impairment (CrCl <30 mL/minute) or moderate hepatic impairment
Vardenafil	Same as sildenafil	10–20 mg on an empty stomach Patients ≥65 years old: 5 mg initially Orally disintegrating tablet (ODT): 10 mg on an empty stomach (no titration) Administration with a high-fat meal may delay absorption 2.5 or 5 mg if coadministered with a strong CYP3A4 inhibitor or an alpha-1 blocker, respectively Dose adjustment for moderate hepatic impairment needed
Tadalafil	Similar onset of action as sildenafil Duration of action up to 36 hours Effective for as-needed **or** daily treatment of organic, psychogenic, or mixed-type ED	10–20 mg if as-needed 10 mg not more than once every 72 hours if coadministered with a strong CYP3A4 inhibitor Dose adjustment for renal or hepatic impairment is necessary when used as needed **or** Daily treatment: 2.5–5 mg once daily (if normal renal and hepatic function) 2.5 mg once daily if coadministered with a strong inhibitor of CYP3A4 or alpha-1 blocker Administration with a high-fat meal does not alter the absorption
Avanafil	Onset 15–30 minutes is more rapid than sildenafil	50–200 mg, 15 minutes to 30 minutes before sexual activity

	50 mg if coadministered with an alpha-1 blocker or moderate inhibitor of CYP3A4 Administration with a high-fat meal may delay absorption

Sildenafil can cause transient “blue vision” in approximately 3% of men. This is caused by the cross-reactivity of the drug with the PDE-6 inhibitor present in the retina.

Rare cases of nonarteritic anterior ischemic optic neuropathy have been reported in men taking sildenafil and tadalafil.

Sporadic reports have indicated a risk of sudden unilateral hearing loss with sildenafil, vardenafil, and tadalafil.

Drug Interactions. All PDE-5Is are contraindicated in men on nitrates. Concurrent use with alpha-adrenergic antagonists causes symptomatic hypotension. Drugs that block the CYP3A4 metabolic pathway can prolong the half-life of sildenafil and thus should be avoided.

Choice of Drug. Current data indicates that all PDE-5Is are of equivalent efficacy and have a similar side-effect profile. Therefore, the choice of agent is based on patient preference, cost, and desired duration of action.

TESTOSTERONE. Testosterone regulates sexual desire and modulates almost every component involved in erectile function. There is a significant overlap between hypogonadism and ED. The diagnosis of testosterone deficiency is made on the basis of the clinical symptoms of hypogonadism, and consistently subnormal serum testosterone concentrations (below 8 nmol/L or 231 ng/dL) at 8 to 10 AM on three occasions.

Testosterone improves libido in men with low testosterone levels but does not necessarily improve ED. As adequate testosterone levels are necessary for NO function, the addition of testosterone to PDE-5Is may improve erectile function in hypogonadal men who did not respond to initial treatment with PDE-5Is alone.

Testosterone is available in different formulations, including oral tablets, transdermal gel/solution or patch, buccal application, subcutaneous implants, and intramuscular injections. Dosing varies depending on the formulation. Dosing is gradually titrated to restore the serum testosterone concentration to a normal range of 13.9 to 27.0 nmol/L or 400 to 700 ng/dL. Monitoring serum testosterone should be done 2 to 3 months after treatment initiation and after changing the dose. Monitoring is then extended to every 6 to 12 months once the dose is stabilized.

Testosterone is contraindicated in men with a history of prostate cancer.

Common side effects of testosterone therapy include exacerbation of benign prostatic hyperplasia, worsening of OSA, erythrocytosis, venous thromboembolism, and skin irritation in patients using the transdermal formulation.

SECOND-LINE THERAPIES. If PDE-5Is are ineffective, second-line therapies include vacuum erection devices, penile injections with vasodilating agents, or intraurethral alprostadil.

Vacuum-Assisted Erection Devices. Vacuum-assisted erection devices are usually tried first as they are less expensive and noninvasive, and some are available over the counter. They apply continuous negative pressure to the penis, drawing blood into the corpora cavernosa, which is then retained by an elastic band applied at the base of the penis. The vacuum erection device may be combined with a PDE-5I to augment the effect of the PDE-5I. Use should be limited to 30 minutes, and caution needs to be exerted in patients who receive anticoagulation treatment. The success rate varies between 60% to 70%, and patient satisfaction ranges between 25% to 49%.

Penile Self-Injection. Intracavernosal injection therapy with alprostadil (prostaglandin E1 [PGE1]) is the only FDA-approved drug for penile self-injection. Alprostadil has vasodilatory properties, which cause inhibition of sympathetic vasoconstriction and direct smooth muscle relaxation, which causes an increased blood flow to the penis. A combination of increased arterial inflow and decreased venous outflow from the corpora cavernosa creates an erection. Off-label compounded mixtures are available in other countries; these include combinations of vasoactive intestinal peptide (VIP) and phentolamine (Invicorp), phentolamine and papaverine (Bimix) with PGE1 sometimes added as a third component (Trimix).

Compounded mixtures have excellent efficacy. Side effects include penile plaque development, penile pain, and priapism.

Intraurethral Alprostadil. Intraurethral administration of alprostadil is a less invasive alternative to intrapenile injection; however, it is more costly and less effective. The alprostadil pellet is inserted into the urethra, and then the penis is massaged for 1 minute. Doses include 125, 250, 500, and 1,000 mcg. Side effects include penile pain and bleeding.

SURGICAL OPTIONS. Surgical management of ED should be reserved for men who cannot use, or who have not responded to, first- and second-line therapies.

Vascular surgery, including arterial bypass and venous ligation surgery, can improve vasculogenic ED. Given that such procedures target the etiology of the ED, in appropriate candidates, the surgery can be curative.

Surgical implantation of an inflatable or malleable (semirigid) penile prosthesis is an invasive and irreversible form of treatment, generally reserved for patients who have failed other types of treatment (third-line treatment).

Premature (Rapid/Early) Ejaculation. Three essential criteria define PE: (1) brief ejaculatory latency; (2) loss of control; and (3) psychological distress in the patient and/or partner. Subtypes include global versus situational, lifelong versus acquired, and coexisting with other SD, including ED. Management depends on the etiology, and approved treatments include SSRIs, topical anesthetics, and psychotherapy for psychogenic factors.

SSRIs are considered first-line treatment: paroxetine (10 to 40 mg/day), sertraline (50 to 200 mg/day), fluoxetine (20 to 40 mg/day), citalopram (20 to 40 mg/day), and escitalopram (10 to 20 mg/day), with paroxetine suggested to be the most effective. The full effect of SSRIs may require 2 to 3 weeks to occur. Clomipramine (12.5 to 50 mg/day) may be tried if SSRIs are ineffective. PDE-5Is may help patients with co-occurring ED. The usual order of treatment in men with coexisting ED and PE is to start with PDE-5Is, then add SSRIs if the patient still has PE.

Tramadol, an analgesic with actions on opioid, serotonin, and norepinephrine receptors, can be used as a third-line treatment but caution needs to be exercised, given the risk of physiologic dependence and respiratory depression.

Topical anesthetics like lidocaine–prilocaine spray have been found to improve ejaculatory latency, ejaculatory control, and sexual satisfaction. Topical alprostadil cream was also found to be beneficial.

Men who have psychogenic PE and/or couples' issues benefit from combined pharmacologic and behavioral treatment as compared to pharmacotherapy alone.

The squeeze technique involves stimulation of the penis until just before orgasm, followed by exerting pressure where the head meets the shaft of the penis to inhibit ejaculation for about 30 seconds and then repeating the steps as desired.

PSYCHOTROPIC-INDUCED SEXUAL DYSFUNCTION AND ITS MANAGEMENT

Psychotropic-induced sexual dysfunction is common but frequently not recognized/addressed in clinical practice. Patients may be reluctant to report this as a side effect, and physicians may not routinely screen for sexual dysfunction or have limited knowledge about its management. Lack of recognition and treatment of sexual dysfunction can negatively impact a patient's quality of life, be an additional source of distress for them and/or their partners, and may ultimately lead to medication nonadherence, which can further exacerbate the psychiatric condition.

The most studied psychotropics with regards to impact on sexual function are antidepressants, given serotonin's role in sexual function. SSRIs and serotonin–norepinephrine reuptake inhibitors (SNRIs) can negatively affect all three sexual response phases. Men more frequently report problems with desire and orgasm, while women more frequently report decreased arousal. A meta-analysis by Serretti and Chiesa suggests that sertraline, venlafaxine, citalopram, paroxetine, and fluoxetine are associated with the highest rates of treatment-emergent sexual dysfunction (with prevalence rates between 70% to 80%); imipramine, phenelzine, duloxetine, escitalopram, and fluvoxamine have lower rates of sexual dysfunction (25% to 45%), but higher than that of placebo. No significant difference from placebo was observed for bupropion, vilazodone, and vortioxetine. Clinical and research use of nefazodone has markedly declined in the United States as a result of the risk of hepatotoxicity.

Bupropion, a dopamine and norepinephrine reuptake inhibitor; buspirone, an agonist of 5-HT1A receptors; and trazodone, a serotonin transporter inhibitor plus 5-HT2A and 5-HT2C receptor antagonist, are not associated with sexual dysfunction. Other atypical antidepressants, including vilazodone and vortioxetine, appear to have lower rates of sexual dysfunction compared to SSRI/SNRIs. Studies on sexual dysfunction related to tricyclic antidepressants and monoamine oxidase inhibitors are scarce, although studies have found that transdermal selegiline has rates of sexual dysfunction comparable to placebo.

When there is evidence of sexual dysfunction in patients experiencing depression, one recommendation is to select a medication with a lower incidence of sexual dysfunction. If sexual dysfunction emerges during the course of treatment with an antidepressant, strategies include switching to a medication with a lower risk of sexual side effects, use of an antidote or medication that will help reverse the sexual dysfunction, waiting for potential resolution/tolerance to the sexual side effect, and lowering the dose of medication. Any of these strategies must be balanced with the risk of exacerbation of psychiatric symptoms. In men, there is evidence supporting the use of PDE-5Is for the treatment of erectile dysfunction induced by antidepressant medications. Bupropion, mirtazapine, and buspirone can be used as augmenting agents to treat antidepressant-induced sexual dysfunction. In a 2013 Cochrane review of the management of antidepressant-induced sexual dysfunction, bupropion (at doses of at least 300 mg daily) was the only medication, aside from the as-needed use of sildenafil in men found to be statistically significant in reversing treatment-emergent SD in both men and women.

Antipsychotic medications can affect all three phases of the sexual response. Sexual dysfunction is thought to occur via dopaminergic antagonism within the tuberoinfundibular system, which causes an elevation in plasma prolactin levels. Head-to-head comparisons are unavailable, but studies suggest that drugs that cause more hyperprolactinemia like risperidone and its metabolite, paliperidone; first-generation antipsychotics (e.g., chlorpromazine, pimozide, thioridazine, thiothixene); and haloperidol are most likely to cause sexual dysfunction. Olanzapine, clozapine, ziprasidone, and quetiapine have slightly lower rates; for olanzapine, this may be dose dependent, with doses >15 mg/day associated with greater sexual dysfunction. Aripiprazole appears to have the lowest incidence of sexual dysfunction compared to other antipsychotics; it may, to some degree, reverse the sexual adverse effects caused by antipsychotics and antidepressants. There is limited but promising data on newer antipsychotics like lurasidone, iloperidone, brexpiprazole, and cariprazine. There is insufficient evidence regarding the treatment of antipsychotic-induced sexual dysfunction. Some authors have proposed dose reduction and switching to a prolactin-sparing second-generation antipsychotic as possible strategies. PDE-5Is may also be of benefit in men with ED. Other treatment strategies include waiting for spontaneous remission or tolerance to the sexual side effects or switching to an antipsychotic less likely to cause sexual dysfunction (aripiprazole). Drug holidays and dose reductions are not recommended due to the risk of psychosis or medication discontinuation.

Limited data is available on sexual dysfunction associated with mood stabilizers. Most of the available data on anticonvulsants originates from studies in epilepsy, which itself can be associated with sexual dysfunction. There is evidence that anticonvulsants that lower bioavailable testosterone (carbamazepine, phenytoin) are more likely to cause sexual dysfunction; this is likely related to the increased metabolism of sex hormones and increased hepatic synthesis of SHBG. Lithium has also been associated with sexual dysfunction, although the mechanism is currently not well understood. Lamotrigine does not appear to cause sexual dysfunction.

There is mixed evidence regarding the use of benzodiazepines and sexual dysfunction. In the treatment of attention deficit hyperactivity disorder (ADHD), there is some evidence that atomoxetine has a greater association with SD compared to placebo.

Mr. J is a 30-year-old man with no active medical problems and a history of Major depressive disorder (MDD) whose initial treatment with a maximum dose of SSRI achieved a partial response. Risperidone 1 mg was added as an inexpensive augmenting agent resulting in full remission of his depressive symptoms. Within a month, he developed ED. No change in the relationship with his wife preceded the ED, but he began to question his attractiveness to his wife and began avoiding sex. Despite his wife's supportive response to his ED, he developed anxiety associated with sexual activity and behavioral avoidance. He did not spontaneously report this side effect to his psychiatrist until questioned directly. The onset of ED seemed to correlate with the addition of risperidone to the high dose of SSRI. Interpersonal issues appeared to be the result of the ED rather than the cause. Medical workup revealed no substance use disorders or recent changes in the use of substances, no cardiovascular risk factors, normal lipid profile and HbA1c, normal testosterone, and slightly elevated prolactin. Sildenafil was added at 50 mg prior to sexual activity. At follow-up, Mr. J reported complete resolution of the ED and remained on the same medication regimen.

Mrs. A is a 32-year-old married woman who complains of a lack of sexual desire since the birth of their second child. She initially thought her lack of interest would recover once the baby started sleeping through the night, but it has persisted for 3 years. She denies relationship difficulties saying she loves her husband, with whom she shares values and communicates well. However, she is worried that her lack of desire might cause a problem due to avoidance behaviors such as avoiding casual intimacy like kissing, going to bed later than her husband, and turning him down about 50% of the time when he approaches her for sex, otherwise participating out of a sense of obligation. When sexually active with her husband, she is able to become aroused and sometimes experiences an orgasm, but this does not increase her desire to have sex the next time. She reports frustration with this problem and is seeking a remedy. She has two children delivered vaginally but no ongoing medical problems or use of daily medications. She has a glass of wine on weekend nights and denies the use of drugs (prescription or illicit drugs). Her husband has had a vasectomy. She exercises regularly, sleeps 7 to 8 hours per night, and is functional at work. She denies depressed or anxious mood. She completed a DSDS which indicates HSDD without current modifiable factors.

If there were identified difficulties that needed to be modified (i.e., relational problems, medical conditions, substances including prescription medications, psychiatric conditions), then these could be addressed, but otherwise, laboratory workup is not warranted in this case. Management can include flibanserin, bremelanotide, and/or mindfulness-based CBT, depending on patient preference.

RECOMMENDATIONS

The evaluation of SD includes a thorough interview with a focus on medical, surgical, sexual, and psychosocial history. Management follows a biopsychosocial approach.

- The treatment for SD should be individualized, taking into account patient and partner's preferences, comorbid conditions, likely etiology of SD, and concomitant medications.
- Treatment starts with addressing modifiable factors (if any).
- There are fewer FDA-approved drugs for female SD versus male SD. Choice of treatment is based on risks versus benefits and patient preference.
- Dosing needs to be adjusted based on the response, and if symptoms persist despite adequate dosing, an additional treatment option should be explored.
- Treatment must include addressing co-occurring depressive disorders.
- Augmentation with bupropion or buspirone may be an option in patients whose depression responded well to an SSRI/SNRI and are experiencing significant SD.
- In patients who did not fully respond to SSRI/SNRI treatment and have significant SD, switching to a medication with less ED risk (mirtazapine, bupropion, vortioxetine, vilazodone) may be the appropriate next step in treatment.

33.18 Psychopharmacology Across the Life Cycle

33.18a Pediatric Psychopharmacology

JEFFREY R. STRAWN, M.D., AND LAURA B. RAMSEY, PH.D.

Psychotropic medications play a critical role in treating many psychiatric disorders in children and adolescents. However, using these medications effectively and appropriately requires an understanding of pediatric pharmacokinetics and pharmacodynamics in addition to the nuances of response that are revealed by numerous double-blind, placebo-controlled trials. These concepts are reviewed in Chapter 53.5, and we review the developmental pharmacology relevant to psychotropic medication use in pediatric populations and the evidence for multiple psychotropics across internalizing and externalizing disorders.

Briefly, pharmacokinetics and pharmacodynamics in children and adolescents differ considerably from adults, and these differences give rise to differences in dosing, differences in response, and differences in tolerability. Importantly, pharmacokinetic and pharmacodynamic factors interact and are mutually influenced by development. These pharmacokinetic factors and pharmacodynamic factors subtend differences in side effects (e.g., extrapyramidal symptoms), dosing (e.g., lithium), and efficacy (e.g., benzodiazepines) between children, adolescents, and adults.

ROLE OF PHARMACOTHERAPY IN CHILDREN AND ADOLESCENTS

While psychotropic medications often play an integral part in the treatment of children and adolescents with psychiatric disorders, they are usually used in combination with other modalities. Depending on the individual, a treatment plan may warrant individual, group, and/or family therapy; educational interventions; parent training; substance use disorder treatment; or any of several additional interventions.

PEDIATRIC ANXIETY AND DEPRESSIVE DISORDERS

Multiple meta-analyses suggest that selective serotonin reuptake inhibitors (SSRIs) are superior to other medication classes for pediatric anxiety disorders. To date, sertraline, fluoxetine, escitalopram, fluvoxamine, and paroxetine have been evaluated in pediatric anxiety disorders. In addition, meta-analyses of SSRIs and serotonin norepinephrine reuptake inhibitor (SNRIs) in youth with anxiety disorders suggest that SSRIs produce faster and greater improvements compared to SNRIs.

For youth with major depressive disorder, multiple randomized controlled trial (RCTs) support the efficacy of fluoxetine and escitalopram in youths with major depressive disorder (MDD)—and both are food and drug administration (FDA) approved for MDD in pediatric patients. Beyond fluoxetine and escitalopram, several other SSRIs have demonstrated efficacy in youth with MDD. However, the use of antidepressant medications in youth must consider the FDA boxed warning that any antidepressant use in children and adolescents and young adults was accompanied by an increased risk for suicidal thinking and behavior, despite most recent meta-analyses failing to replicate the original analyses from 2004.

PHARMACOTHERAPIES FOR BIPOLAR DISORDER AND SCHIZOPHRENIA IN YOUTH

Placebo-controlled studies suggest that multiple mixed dopamine and serotonin receptor antagonists are efficacious in pediatric patients with acute mania, and six agents have received FDA approval for pediatric mania (lithium, risperidone, aripiprazole, quetiapine, olanzapine, and asenapine). In general, antimanic effects are observed within the first 2 weeks of treatment and mood stabilizers may be used as second-line treatments or in combination with mixed dopamine receptor antagonists. While the anticonvulsants likely have primary roles in the treatment of adults with bipolar disorder, these agents have produced very mixed results in youths.

Aripiprazole, lurasidone, olanzapine, quetiapine, risperidone, and paliperidone have received FDA approval for the treatment of adolescents with schizophrenia aged 13 to 17 years. The mixed dopamine–serotonin receptor antagonists are considered first-line medications for adolescents with schizophrenia. Studies involving clozapine (Clozaril) in treatment-refractory early-onset schizophrenia spectrum disorders have demonstrated the superiority of clozapine compared to haloperidol and olanzapine, with regard to reduction in negative symptoms and, to a certain degree, with the overall response.

ATTENTION DEFICIT HYPERACTIVITY DISORDER (ADHD)

Dopamine/norepinephrine reuptake inhibitors—including both amphetamine- and methylphenidate-based agents are highly efficacious in treating youth with attention deficit hyperactivity disorder (ADHD). In general, 65% to 75% of stimulant-treated youth response and response rates are similar for methylphenidate and amphetamine in immediate-release as well as extended-release preparations.

In addition to stimulants and norepinephrine reuptake inhibitors (e.g., viloxazine and atomoxetine), multiple RCTs support the efficacy of extended-release preparations of clonidine and guanfacine as monotherapy in children and adolescents with ADHD.

CONSIDERATIONS FOR EFFECTIVE PHARMACOTHERAPY IN CHILDREN AND ADOLESCENTS

There is substantial evidence for pharmacologic treatments for psychiatric disorders in children and adolescents. Pharmacokinetics and pharmacodynamics in children and adolescents differ considerably from adults, and these differences give rise to differences in dosing, differences in response, and differences in tolerability. As such, safe and effective use of pharmacotherapy requires an understanding of pediatric pharmacokinetics and pharmacodynamics in addition to the nuances of response that are revealed by numerous double-blind, placebo-controlled trials.

33.18b Biologic Therapies: Geriatric Psychopharmacology

Ari B. Cuperfain, M.D., M.Sc., and Bruce G. Pollock, M.D., Ph.D., F.R.C.P.C.

Sixteen percent of the U.S. population who are older than age 65 consume 40% of prescription drugs. This polypharmacy is ubiquitous, and indeed, the most common treatable illness in older adults is due to the numerous medications (including prescribed, over the counter, and herbal) that they take. Not infrequently, prescribing cascades occur when additional medications are added to treat the side effects of prior medications. The Beers criteria lists medications that are inappropriate for older adults. Wherever possible, physicians should deprescribe inappropriate or less essential medications. This is often difficult to do, and deprescribing.org can provide some guidance on this process.

Pharmacokinetic and pharmacodynamic changes associated with aging and illness render older patients more sensitive than younger adults to the adverse effects of medications. The most common age-associated changes affecting pharmacokinetics are related to distribution and excretion.

With age, adipose tissue increases proportionally compared to body water in an older adult due to a loss of muscle mass. Thus, the volume of distribution and half-life for lipid-soluble drugs (most psychotropics) increases while it decreases for water-soluble drugs (e.g., lithium, digoxin [Lanoxin]). Lipid-soluble drugs, especially those with long half-lives (e.g., diazepam [Valium], clonazepam [Klonopin], aripiprazole [Abilify]), accumulate in fat and clear more slowly from the body. For water-soluble drugs, the therapeutic window shrinks as transient increases in plasma concentrations are less effectively buffered. Plasma proteins (e.g., albumin) can also decrease with age, meaning drug concentrations for highly protein-bound drugs (e.g., valproic acid [Depakote]) are less reliable.

For excretion, the average glomerular filtration rate decreases by 50% between the ages of 20 and 70 years. Decreased renal clearance may require dose adjustment for drugs (or metabolites) that are renally cleared, most notably lithium, but also others, including gabapentin (Neurontin), pregabalin (Lyrica), topiramate (Topamax), amantadine (Symmetrel), paliperidone (Invega), memantine (Namenda), rivastigmine (Exelon), and desvenlafaxine (Pristiq). Moreover, excretion can be further impaired by commonly used nonsteroidal anti-inflammatory drugs (NSAIDs) and angiotensin-converting enzyme (ACE) inhibitors.

Although there is no uniform age-associated decline in cytochrome P (CYP) 450 enzymes, reductions in hepatic mass and blood flow place greater emphasis on interindividual differences in drug metabolic capacity as well as reducing clearance of normally high-clearance CYP3A4 metabolized drugs. Psychotropics metabolized by this isozyme include alprazolam (Xanax), sertraline (Zoloft), and mirtazapine (Remeron). Inhibition or induction of enzymes, often due to drug–drug interactions, cause wide variation in drug concentrations. It is important to recognize isozyme specificity in CYP drug metabolism and then to know which medications may interact with a given isozyme. For example, CYP1A2 metabolizes clozapine (Clozaril), asenapine (Saphris), olanzapine (Zyprexa), and fluvoxamine (Luvox). 2D6 metabolizes duloxetine (Cymbalta), venlafaxine (Effexor), paroxetine (Paxil), brexpiprazole (Rexulti), risperidone (Risperdal), and many tricyclic antidepressants. 2C19 metabolizes diazepam and phenytoin (Dilantin). Phase II metabolism in older patients is understudied, although it may also decrease with age.

Pharmacodynamic considerations must also factor into clinical decision making. The density of drug targets, such as the dopaminergic and cholinergic receptors, is generally reduced, resulting in increased sensitivity to D2 antagonists and antimuscarinic agents. Reduced β-receptor sensitivity contributes to diminished baroreceptor reflex responses, exacerbating orthostatic hypotension in response to α2-agonists and other drugs. Atypical antipsychotics have been shown to increase mortality in patients with dementia. Constipation is a common side effect of many psychotropic medications and should be monitored. Risks of bleeding and hyponatremia with selective serotonin reuptake inhibitor (SSRI) treatment are more pronounced in older adults. All psychotropics may increase the risk of falls and may increase cognitive impairment in older patients. In addition to prescribed medications, older adults are also more sensitive to recreational substances and over-the-counter nutraceuticals, and these may figure in drug interactions. Future areas for innovation include disease-modifying agents for Alzheimer disease and increased representation of older adults in clinical trials.

33.19 Biologic Therapies Around the Globe

33.19a Essential List of Medicines

Sasson Zemach, M.D., Daniel Minkin Levy, M.D., and Joseph Zohar, M.D.

Similar to all other fields of medicine, therapeutic options in psychiatry differ greatly worldwide. While the biologic therapies section reflects the current treatment options in the North American and Western European continents, the case is naturally different in the developing world and in regions of distinct cultural differences. The “Biologic Therapies Around the Globe” subsection aims to give a brief introduction to the current tools available in three central regions: Africa, India, and Latin America (mostly Brazil).

THE ESSENTIAL LIST OF MEDICINES

In order to obtain a basic “package” of vital medications, health care systems create national lists of essential medicines (nEML). These commonly rely on the infrastructure of the World Health Organization (WHO)’s Essential Medicines List (EML). First issued in 1977, The EML model is a recommendation document published biannually and includes the basic medications needed to “satisfy the priority health care needs of the population” (from the WHO website). According to the WHO website, “essential medicines are selected with due regard to disease prevalence and public health relevance, evidence of clinical efficacy and safety, and comparative costs and cost-effectiveness.”

The 22nd version was published in September 2021. It is divided into a core list, namely a basic list of the most efficient, safe, and affordable drugs, and a complementary list which includes medications that are too essential but require specific care of specialized facilities/require special training/consistently more costly or maybe less cost-effective.

Table 33.19a–1.

A Modified Table of the WHO’s Essential List of Medicines Recommended for Mental and Behavioral Disorders

Drug	Dosage and Preparation	Comments
Medicines Used in Psychotic Disorders		
Chlorpromazine[a,b]	**Injection:** 25 mg/mL (hydrochloride) in 2 mL ampoule **Oral liquid:** 25 mg/5 mL (hydrochloride) **Tablet:** ***10 mg; 25 mg; 50 mg; 100 mg (hydrochloride)***	Restricted use in children and adolescents
Fluphenazine[a]	**Injection:** 25 mg (decanoate or enantate) in 1 mL ampoule	
Haloperidol[a,b]	**Injection:** 5 mg in 1 mL ampoule **Tablet:** 2 mg; 5 mg	Restricted use in children
Paliperidone[a]	**Injection (prolonged-release):** 25 mg; 50 mg; 75 mg; 100 mg; 150 mg (as palmitate) in prefilled syringe	Therapeutic alternatives: - risperidone injection
Risperidone[a]	**Solid oral dosage form:** 0.25–6.0 mg	
Clozapine[b]	***Solid oral dosage form: 25–200 mg***	
Medicines Used in Mood Disorders		
Medicines used in depressive disorders		
Amitriptyline[a]	**Tablet:** 25 mg; 75 mg (hydrochloride)	
Fluoxetine[a,b]	**Solid oral dosage form:** 20 mg (as hydrochloride)	Use in children requires special training; age restriction >8 years Therapeutic alternatives: - citalopram - escitalopram - fluvoxamine - paroxetine - sertraline
Medicines used in bipolar disorders		
Carbamazepine[a]	**Tablet (scored):** 100 mg;	

	200 mg	
lithium carbonate[a]	**Solid oral dosage form:** 300 mg	
valproic acid (sodium valproate)[a]	**Tablet (enteric coated):** 200 mg; 500 mg	***Avoid use in pregnancy and in women and girls of childbearing potential, unless alternative treatments are ineffective or not tolerated because of the high risk of birth defects and developmental disorders in children exposed to valproate in the womb***
Medicines for Anxiety Disorders		
Diazepam[a]	**Tablet (scored):** 2 mg; 5 mg	
Medicines Used for Obsessive-Compulsive Disorders		
Clomipramine[a]	**Capsule:** 10 mg; 25 mg (hydrochloride)	
Medicines for Disorders due to Psychoactive Substance Use		
Bupropion[a]	**Tablet (sustained release):** 150 mg (hydrochloride)	
Nicotine replacement therapy (NRT)[a]	**Chewing gum:** 2 mg; 4 mg (as polacrilex) **Transdermal patch:** 5–30 mg/16 hours; 7–21 mg/24 hours	
Varenicline[a]	**Tablet:** 0.5 mg, 1 mg	
Methadone[b]	***Concentrate for oral liquid: 5 mg/mL; 10 mg/mL (hydrochloride)*** ***Oral liquid: 5 mg/5 mL; 10 mg/5 mL (hydrochloride)***	Therapeutic alternatives should be considered, ***Therapeutic alternatives:*** ***- buprenorphine***

---

[a] Core list.

[b] Complimentary list. Medications may be included both in the core list and complimentary list. Information is retrieved from the WHO's full Essential List of Medicines issued at Sep. 2021.

Overall, of the 479 medications included (September 2021), 17 medications for mental and behavioral disorders are included (Table 33.19a–1).

Parallel to the call for a broadening of the list to meet the global burden of psychiatric disorders (mainly depression and attention deficit hyperactivity disorder [ADHD]), the criteria for inclusion of new agents remain complex and multifactorial. In 2018, the American Psychiatric Association (APA) approved an action plan aimed to help revise the EML in collaboration with the WHO to help provide well-founded recommendations. Nevertheless, the list is updated gradually, with risperidone and clozapine added in 2013 and paliperidone long-acting injectables (LAIs) added in 2021, along with bupropion and varenicline for the indication of smoking cessation.

In summary, EML helps to ensure a sufficient level of health and is related to the increased understanding that a feasible standard of health, including mental health, is a global necessity and a global responsibility.

33.19b Biologic Therapies in Africa

OYE GUREJE, PH.D., D.SC., F.R.C.PSYCH., F.W.A.C.P., AND OLATUNDE AYINDE, M.B.B.S., M.S., F.W.A.C.P.

The major mental disorders are present wherever they have been sought in Africa. Even though rates may vary within the continent and sometimes differ from what has been reported in other parts of the world, most of the disorders described in both DSM-5 and ICD-11 have been identified in populations across the continent. These similarities with other parts of the world would suggest that considerations of biologic therapies as they apply in those parts will also be relevant to Africa. However, features that may affect drug metabolism and that may differ between population groups could produce substantially different profiles of efficacy and side effects and therefore require a need for specific consideration of biologic therapies in Africa. Examples of such features with a potential effect on the mechanisms of action of biologic therapies are genetics, lifestyles, diet, and the age structure of the population. Beyond these potential differences in the metabolism or mechanisms of action of biologic therapies, factors that may be of far greater relevance are those associated with cost, availability, and access. These factors may have a profound impact on the utility of specific therapies in ways that go beyond their biologic profile.

Africa is diverse in regard to culture, social norms and practices, and also in respect to the organization of the health systems of the countries on the continent. Any discussion of the continent about therapeutics and health care will therefore have to be considered as providing broad generalizations. This chapter is thus an attempt to provide such a broad picture that is nevertheless informative. In doing so, it should be made clear that no allusion is being made to any form of racial similarity between the populations resident on the continent or to possible differences between them and the rest of the world. Our current knowledge cautions against any such simplistic use of race, a concept that has essentially been rendered obsolete by genetics.

OVERVIEW OF THE EFFICACY AND SIDE EFFECTS OF BIOLOGIC THERAPIES IN AFRICA

Only a few studies have compared the efficacy and side-effect profile of different forms of biologic therapies among Africans. An early study of the correlation between chlorpromazine metabolism and clinical response among Nigerian patients with schizophrenia identified three groups: responders, nonresponders who subsequently improved with haloperidol, and nonresponders who improved with electroconvulsive therapy (ECT). A study in South Africa that compared oral antipsychotics, specifically haloperidol or risperidone, with risperidone long-acting injection among patients with early psychosis found the latter to have advantages in terms of efficacy and fewer extrapyramidal symptoms but was associated with more weight gain. An open-label study conducted in Nigeria comparing patients treated with a combination of ECT and pharmacotherapy with first-generation antipsychotics with those who received pharmacotherapy alone found that the former had a shorter duration of hospitalization even though they were more likely to report subjective but short-lived memory impairment. A study conducted in Malawi found adverse drug reactions to be common among patients receiving chlorpromazine or haloperidol, with more severe reactions among males, patients aged 35 years or more, and those receiving chlorpromazine. Thus, and in general, the findings of these studies have generally been broadly like what has been reported from other groups across the world. This general observation is supported by the results of a systematic review of 26 studies of antipsychotic medication in Africa, which found improvement in psychiatric symptoms with use, frequent occurrence of side effects, including metabolic syndrome, and a common difficulty with adherence by patients with severe mental disorders.

A few studies have sought to explore the use of biologic therapies in the context of some peculiarities of the continent. An important consideration is the concurrent use of psychotropics with medication for physical health conditions that are common in Africa. In this regard, an early study found marked increases in the plasma levels of chlorpromazine when used concurrently with antimalarial agents, thus raising the possibility of an elevated risk of toxicity. Unfortunately, no subsequent exploration of this interaction has been reported in the literature. Along the same line, and given the common co-occurrence of psychiatric illness and HIV and evidence suggesting increased incident neurocognitive impairment among a subset of persons with this comorbidity, studies exploring the effectiveness of psychotropic medications in persons living with HIV are needed. The potential interactions between cytochrome P450 metabolism and the nonnucleoside reverse-transcriptase inhibitors provide a good justification for such studies.

SPECIFIC EXAMPLES OF PSYCHOTROPIC MEDICATIONS

Both first-generation antipsychotics and newer medications in oral (haloperidol, quetiapine, ziprasidone) and depot preparations (flupentixol, risperidonem, and ziprasidone) have been shown in a systematic review of cohort studies and randomized trials to be effective in reducing symptoms and improving functioning in African patients with psychosis. A better response was predicted by a shorter duration of illness, less comorbidity, less cognitive impairment, fewer negative symptoms, good premorbid functioning, and medication adherence. Relapses appeared to be associated with reduced effectiveness of antipsychotic medications. Extrapyramidal side effects (EPSE) were more likely in patients taking first-generation antipsychotics, while metabolic side effects and hyperprolactinemia were more associated with second-generation medication use. In a study conducted in Ethiopia among a cohort of 312 patients with bipolar disorder, being on both antipsychotics and antidepressants for more than 50% of the average follow-up period (2.5 years) or longer was a strong predictor of remission. Another study found that treatment-emergent EPSE was associated with spontaneous neurologic soft signs in antipsychotic-naive Yoruba Nigerians and Xhosa South Africans with schizophrenia.

The most commonly used antidepressants in most African settings are tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs). For example, a study from South Africa indicates that TCAs and SSRIs are the most prescribed medications in the child and adolescent population, with amitriptyline and fluoxetine being the drugs of choice. In regard to comparative efficacy, a Nigerian trial comparing moclobemide (max dose 600 mg/day) to amitriptyline (max dose 150 mg/day) in 60 subjects found both to be safe and effective in treating depression, with no statistically significant difference between the two.

Anticonvulsants in common use in African settings include carbamazepine, sodium valproate, phenytoin, and lithium, with the commonest indication being epilepsy and mood disorders. A common difficulty with the use of lithium salt is the lack of the required laboratory backup to monitor patients or the inability of the patients to pay for the service. Payment out of pocket, a common way to access service in much of Africa, is indeed a major reason why adherence to treatment and related care remains a major problem in many settings in Africa.

ELECTROCONVULSIVE THERAPY

ECT is widely used in Africa. In Nigeria, for example, its use dates to the 1970s. A study published in 2015 reports the widespread availability of ECT in South Africa and indicates that, despite lingering challenges with access and training, its use follows international guidelines. Studies show a good attitude to ECT by psychiatrists of African origin. ECT has been used to manage patients with schizophrenia, mania, and severe depression, with those with poor response to medication or who have psychomotor retardation being the most likely to be prescribed the treatment. An early controlled study in Nigeria did not find any significant difference in symptom remission between two groups of patients with schizophrenia on antipsychotics (n = 20) who took six sessions of real or sham ECT, with both groups recording improvement over a 20-week follow-up period. An uncontrolled study in Malawi, however, found up to 90% improvement in a mixed population of 47 patients. The most common side effects reported in the study included cognitive problems (confusion and amnesia), muscle aches, headache, and lesions of the oral cavity.

Modified bilateral ECT has largely replaced unmodified administration that was common in the early days of ECT use on the continent. The average number of treatments in one Nigeria tertiary center is six. Patients appear to accept ECT, even when unmodified, and acknowledge its benefits, despite complaints of not being well informed about the procedure and deficiencies in ECT service delivery.

TRANSCRANIAL MAGNETIC RESONANCE STIMULATION

Transcranial Magnetic Stimulation is very rarely used on the continent, with only limited use in South Africa and in Nigeria, where it has only recently become available in one private clinic in Lagos. A recent study found accelerated theta-burst repetitive transcranial magnetic stimulation led to improvement in depressive symptoms by the eighth day of treatment in nine patients who underwent the procedure. Mild headache was the most commonly reported adverse effect.

ATTITUDES OF PATIENTS AND CLINICIANS TO PHYSICAL THERAPIES

Studies from different parts of Africa report good attitude toward antipsychotics among persons with psychosis, with better attitude reported when the formulation of choice matches the current formulation the patient is on, there is a relative absence of side effects, the patient has good insight and comes from a higher income household. On the other hand, a short duration of illness and the presence of side effects are associated with poor attitude. There are suggestions that patients may not be well educated by their physicians on the role of their medications in treatment. One study from Nigeria found that out of 200 patients, about three-quarters did not know the role of Benzhexol (Artane) in their treatment. Lack of information may partly explain the poor medication adherence that has been reported among patients on oral antipsychotics in some settings.

In the 1980s, the most widely prescribed antipsychotics in Nigeria were chlorpromazine, thioridazine, and trifluoperazine; antidepressants, amitriptyline and imipramine; anxiolytic, diazepam and chlordiazepoxide. This pattern has only changed to a limited extent in recent times and may also reflect the practice in many other parts of Africa. With the availability of generic forms, the use of second-generation antipsychotics has now become common on the continent. Still, polypharmacy is common among many clinicians. One study from Nigeria found that more than 50% of 320 outpatients were prescribed a combination of depot first-generation antipsychotics and oral second-generation medications. The commonest depot medications in use are fluphenazine and Flupentixol. As highlighted by Adeponle et al., polypharmacy encourages waste and has the potential to increase the financial burden on patients receiving care in low-income settings.

PHARMACOECONOMICS

Even though psychotropic drugs are becoming more available in sub-Saharan Africa, there are still several hurdles to cross before they are widely affordable to the majority of end users. Newer medications often take very long to be licensed for widespread availability and are very costly and therefore not cost-effective. In many parts of Africa, out-of-pocket payment is still the predominant mode of payment for services and medications, and even when these medications are covered by health insurance, newer, costly drugs are not stocked by most health facilities. There is also a high prevalence of counterfeiting. For example, in one report, more than 50% of all drugs on sale in Nigeria were either fake or substandard. Similar experiences have been reported in Gabon, Kenya, and Madagascar concerning anticonvulsants specifically. This had been attributed to drugs being manufactured in China, as well as poor storage in some cases, among other factors. In some settings, essential psychotropic medications are not available in public health facilities.

Cost-effectiveness studies of interventions for major psychiatric disorders are still very few in Africa. Recent studies have sought to compare total mental health care costs between task-shared care and routine care rather than focusing on the pharmacoeconomics of specific biologic therapies. In general, packages of intervention consisting of first-generation antipsychotics and TCAs have been reported to be more affordable in many African settings. In regard to what proportion of the total cost of receiving care might be due to the direct cost of medication, an early study in Nigeria by Suleiman et al. suggests that this could be about 53% in the case of schizophrenia. A more recent study in Nigeria found that the cost of medications constituted 51.2% of the direct cost and 21.9% of the total cost of Schizophrenia.

33.19c Biologic Therapies in India

E. MOHANDAS, M.B.B.S., M.D., SANDEEP GROVER, M.B.B.S., M.D., AND AJIT AVASTHI, M.B.B.S., M.D.

India is a large country of 28 states and eight union territories with a population of 1.39 Billion (139 Crores). India has less than 10,000 psychiatrists (although 900 psychiatrists graduate every year), short of 27,000 to reach the desirable minimum of 3 psychiatrists per 100,000 population. According to the recent National Mental Health Survey (NMHS), the lifetime prevalence of mental disorders is 13.7%, and the current prevalence is 10.6%. India ranks 3rd worldwide for pharmaceutical production by volume and 14th by value. The domestic pharmaceutical industry has a strong network of 3,000 drug companies and about 10,500 manufacturing units. Newer antipsychotics like lumateperone and brexiprazole are still not available in India. Almost all psychotropics are available at affordable rates. Long-acting antipsychotic preparations, including risperidone, olanzapine, and paliperidone, are available with the expectation of aripiprazole and once-in-3 months paliperidone reaching the market soon. The use of agomelatine, lurasidone, vilazodone, vortioxetine, and levomilnacipran is minimal due to the cost factor or lack of expected efficacy. Neuroscience-based nomenclature (NbN), although initiated in some academic sessions, needs to be disseminated further for a better understanding of prescription principles.

Considering somatic treatments, electroconvulsive therapy (ECT) is widely used in India, and over the last decade, many centers have provided other brain stimulation techniques, such as repetitive transcranial brain stimulation (rTMS), transcranial direct stimulation (tDCS), and deep brain stimulation.

Despite the availability of various treatment modalities at an affordable price, there is a wide treatment gap (70% to 92%) for various mental disorders. The cost of illness studies suggests that the cost of illness of disorders like schizophrenia and bipolar disorder is significantly lower in India when compared to the data from Western countries, and the cost of treatment of schizophrenia is comparable to the cost of illness of diabetes mellitus. Treatment guidelines by any professional organization for the management of various psychiatric disorders were nonexistent two decades back. However, the Indian Psychiatric Society has initiated publishing management guidelines on various psychiatric disorders since 2005. Multicentric studies on prescription patterns suggest that among the various antidepressants, escitalopram and sertraline are the most commonly prescribed antidepressants. The multicentric study that evaluated the prescription patterns found that olanzapine was the most commonly prescribed antipsychotic medication, followed by risperidone. On the other hand, a survey of psychiatrists suggested that risperidone, olanzapine, and haloperidol were the three most commonly prescribed antipsychotics. Clozapine is, in general, underutilized due to the fear of side effects and the need for monitoring. The cross-national studies, however, suggest that prescription rates of clozapine are comparable to other Asian countries. Long-acting injectable (LAI) antipsychotics are also used less often, with prescription rates for the same during the acute phase of illness being 9.3% and 18.4% during the stable/stabilization phase of schizophrenia. First-generation LAIs are used more often than second-generation antipsychotic LAIs. The LAIs are mostly used in patients who have a history of medication and treatment nonadherence. The cross-national studies, which involved centers from India, suggest that prescription rates of LAI antipsychotics in India are much lower than in countries like Malaysia, Singapore, Sri Lanka, and Pakistan.

The studies evaluating prescription patterns of patients with bipolar disorder seen for the first time suggest that valproate is more often used when compared to lithium, whereas studies that have included clinically stable patients of long duration of illness suggest a small difference in the prescription pattern for valproate and lithium. Across the various disorders, there is a high prescription rate for the prescription of benzodiazepines during the acute phase of illness. Available data also suggest low prescription rates for polypharmacy (i.e., prescription of more than one agent from the same class of medications).

With regard to the therapeutic drug monitoring (TDM) facilities, serum lithium level estimation is most widely available. Estimation of serum valproate and carbamazepine, although available across the country, is not performed frequently as estimation of serum lithium levels. Serum clozapine level estimation facilities are limited, and estimation of other antipsychotic levels is nonexistent.

Till recently, both modified and unmodified ECT was used for patients with severe mental disorders in India. However, the Mental Health Care Act of 2017 banned the use of unmodified ECT in the country. A survey published in 2005 showed that ECT services were available in a majority of the teaching institutions, with brief pulse being used in more than half of the institutes and bilateral ECT being used in almost all the institutes. Available data on indications for ECT revealed that the most common diagnostic group was schizophrenia (36.5%), followed by depression (33.5%) and mania (17.9%). Adult patients in the age group of 45 to 64 years formed the largest proportion of patients receiving ECT in contrast to the older adult group (14.7%, aged ≥65 years). Researchers from India have evaluated the various techniques to improve the safety of the use of ECT in patients with mental disorders. Emerging data from India also suggest that combining clozapine with ECT may be beneficial in the management of patients with clozapine-resistant schizophrenia.

In the last decade, neurostimulations like rTMS and tDCS have been added to the therapeutic armamentarium in selected centers. The preliminary studies cite the safety and efficacy of rTMS in the management of negative symptoms in patients with schizophrenia. Indian studies have found the usefulness of tDCS in the management of treatment-resistant obsessive-compulsive disorder and refractory auditory verbal hallucinations in schizophrenia.

Overall, the biologic therapies available for the management of various psychiatric disorders in India are at par with most developed countries, and the overall cost of treatment of mental disorders is much lower than in developed countries. Currently there are no registries for proper guidance about the effect of psychotropics in special population like children, elderly, pregnancy and postpartum. In India, the private sector contributes to a significant proportion of mental health services. However, limited data is available in terms of the use of psychotropics and various somatic treatments in the private sector.

33.19d Biologic Therapies in Latin America

RODOLFO FURLAN DAMIANO, M.D., PH.D., AND ANDRÉ RUSSOWSKY BRUNONI, M.D., PH.D.

Even though there are several well-known Latin American researchers both currently and in the history of medicine, the economic status of the continent impairs a greater development of the field. Furthermore, limited resources impact the development and availability of new drugs to the whole continent, being both unavailable or unaffordable to the majority of the population. This heterogeneity in the medication market throughout the globe justifies chapters outlining the biologic therapies available in each continent. Moreover, due to the markedly cultural and economic differences among countries in Latin America, as well as in drug regulation policies within some countries, we chose to focus, in this chapter, on biologic therapies available in Brazil (due to the citizenship of the authors) in order to serve as a model to other Latin American countries, despite knowing that this pretentious task is almost unreachable.

PREVALENCE AND GAP IN TREATMENT OF MENTAL DISORDERS

The 12-month prevalence of any mental disorder in Latin America is 17%, varying from 7.2% in Guatemala to 29.6% in Brazil, which is higher than in the United States (26.2%). Severe mental disorders follow the same pattern, with a 12-month mean prevalence of 4.9%, varying from 2% in Guatemala to 10% in Brazil. Suicide follows a different pattern, with Guyana (26.07/100.000), Suriname (24.78/100.000), Uruguay (16.82/100.000), Argentina (10.61/100.000), Chile (10.14/100.000), Ecuador (9.21/100.000), Venezuela (8.68/100.000), and Bolivia (6.41/100.000) having an incidence greater than Brazil (6.09/100.000), despite the large number of mental health disorders found in Brazil.

The treatment gap is another important issue that might also explain this contrast between mental disorders versus suicide among countries. The weighted mean for treatment gap in Latin America is 79.0% for any mental disorder, with a smaller gap found in Chile (61.5%) and a larger gap in Colombia (86.1%). For severe mental disorders, the treatment gap is a little smaller (69.9%), with Guatemala representing a large number of untreated individuals (86.9%). Due to the social inequality in Latin America, special attention should be given to minorities (e.g., indigenous) that represent important vulnerable populations usually neglected. Also, several countries do not have reliable data, representing an urgent area for research and public policies.

PARTICULARITIES IN DRUG TREATMENT AND DRUG RESPONSE

Brazil and Latin America represent a “world in a continent” due to the remarkable cultural differences. It might impact several different areas, such as pharmacotherapy, patient care, and ethics, for example. Noteworthy, pharmacogenetic polymorphisms represent one important and usually forgotten therapeutic challenge in Latin America, impacting drug response and side effects. Pharmacogenetic studies should be conducted in Brazil, and the generability of North American and European studies should be viewed with caution.

Another particularity of drug treatment in Latin America is the presence of diverse religious backgrounds and medicinal plants. Religious affiliation might impact the way the biologic treatment is seen and conducted (e.g., faith healings; electroconvulsive therapy; ethics), sometimes influencing the treatment choice. Moreover, the diversity of medicinal plants also represents an important feature, as many patients use it without prescription, having important (positive and negative) short- and long-term mental health consequences that deserve closer attention from researchers.

OTHER BIOLOGIC THERAPIES

Electroconvulsive Therapy and Magnetic Seizure Therapy

Electroconvulsive therapy (ECT) has been used in Brazil since the 1930s, with the first publication of clinical results by the founder of the Institute of Psychiatry—Clinics Hospital, Prof. Pacheco Silva, following an increased use in academic institutions and asylums and less frequently after the introduction of antipsychotics in the 1970s. ECT in Brazil is restricted to a few current university services (14 academic centers), leaving critically ill patients without access to this important therapeutic resource. There is an important lack of public assistance for ECT, which affects mainly poor and severely ill patients, resulting in overcrowded services handled by brave colleagues offering their best skills even with poor resources and sometimes enduring unfair criticism on their important work. In early 2021, the first magnetic seizure therapy (MST) device was introduced in São Paulo, Brazil, at the Institute of Psychiatry, being solely available for research purposes.

Repetitive Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (rTMS) was approved by ANVISA in 2010, just after the U.S. FDA approval, and by the National Medical Board (CFM) in 2012, making Brazil one of the first countries in the world to have rTMS introduced as a clinical (not experimental) treatment. Currently, MagVenture (Denmark), Neurosoft (Russia), and Magstim (U.K.) are ANVISA cleared and are used in almost all clinical and research centers in Brazil. In fact, there are more than 100 private practice centers that perform rTMS in many locations in Brazil. Unfortunately, rTMS is covered by neither health insurance nor the Brazilian Universal Health System (SUS), which is a huge limitation for access.

Transcranial Direct Current Stimulation (tDCS)

Several transcranial direct current stimulation (tDCS) devices have been ANVISA approved between 2017 and 2021 in Brazil, such as the Depression LTE system (SoterixMedical, USA), DC-Stimulator Plus (Neuroconn, Germany), and Flow (FlowNeuroscience, Sweden). tDCS might represent a nonexpensive neuromodulatory strategy to be used both by patients and providers in a low/middle-income country (LMIC) scenario such as Brazil; therefore, there are more than 200 private practice centers that offer tDCS services. However, here the issues of off-label use and low level of evidence are even more of concern, which is summed by an unclear regulatory status by the Medical Board that has not yet legislated on the indications and contraindications of tDCS in medical practice, hindering all tDCS applications essentially off-label and decided on an individual medical basis.

33.20 Brain Stimulation

33.20a Electroconvulsive Therapy

Joan Prudic, M.D.

Electroconvulsive therapy (ECT), also known as electroshock therapy, is a standard psychiatric treatment in which electricity is delivered through the scalp to induce a therapeutic seizure. First conducted in 1938 by two Italian physicians, Ugo Cerletti and Lucio Bini, on patients with schizophrenia, ECT has become the oldest somatic treatment for many psychiatric conditions, including depression, catatonia, as well as bipolar disorder and schizophrenia. ECT is generally reserved for patients who have failed to respond to pharmacotherapy or have adverse reactions to standard pharmacotherapy, as well as those with severe symptoms such as suicidality, psychosis, or grave functional impairment, resulting in a need for a rapid and definitive response. It is estimated that about 5–8/100,000 residents in the United States receive ECT annually. Contrary to the sometime negative depiction of ECT, its safety and efficacy has been much improved with modification of various aspects of the technique such as optimization of the stimulus energy, electrode placement, the use and optimization of general anesthesia, as well as improvement in cardiopulmonary management. The application of ECT is regulated by the FDA, and there are regulatory and professional guidelines for proper consent procedures including situations where the patient lacks capacity. The mechanism of action of ECT remains an active area of hypothesis and research, although a great deal of information has been obtained with the availability of newer research tools.

HISTORICAL OVERVIEW

Convulsive therapies for major psychiatric illnesses predate the modern therapeutic era with the use of camphor reported as early as the 16th century, and several accounts of camphor convulsive therapies from the late 1700s to the mid-1800s. With the success of malarial fever therapy for general paresis, interest in biologic therapies for psychiatric illnesses increased in the early 20th century. By the 1930s, insulin coma and psychosurgery had also been introduced.

Unaware of the history of camphor convulsive therapy, Meduna made the observation that the brains of epileptics had greater than normal numbers of glial cells, while those of schizophrenics had fewer, and hypothesized that there might be a biologic antagonism between convulsions and schizophrenia. Following animal experimentation, camphor was (again) selected as the appropriate agent to use for the therapeutic induction of seizures. In 1934, the first catatonic psychotic patient was successfully treated using intramuscular injections of camphor in oil to produce therapeutic seizures. Thirteen of a series of 26 patients treated similarly were reported to have had some degree of remission of psychosis. In 1937, a conference on convulsive therapies and insulin coma was held in Switzerland and the use of convulsive treatments spread.

Although effective, camphor was relatively long acting and was soon replaced by pentylenetetrazol. This agent was also associated with problems, principally patient rejection of the noxious sensations associated with GABA antagonism while conscious, for example, increased heart rate, feelings of terror, and myoclonus preictally.

Bini and Cerletti were interested in the use of electricity to induce seizures, and, after a series of animal experiments and observation of the use of electricity commercially, were able to safely apply current across the heads of animals for this purpose. In 1938, the first electroconvulsive treatment (ECT) course was administered to a delusional and incoherent patient, who improved with one treatment and remitted after 11 ECT. Electrical induction of convulsive therapy could be made more reliable and shorter acting than chemically induced convulsive therapies, and, by the early 1940s, had replaced them. In 1940, the first use of ECT occurred in the United States.

Throughout the 1940s, ECT was a first-line therapy for a variety of major psychiatric illnesses. In the ensuing decades, efforts to improve its acceptability and safety profile continued. In 1940, A. E. Bennett developed curare for use in the prevention of ECT-associated fractures, which had previously resulted from the severe muscle contractions associated with the tonic phase of the seizure induction. By the 1950s, brief general anesthesia with succinylcholine replaced curare. Other improvements in anesthesia, most notably oxygenation throughout the treatment session and cardiac and oxygen saturation monitoring became standard. Efficacy in disorders other than schizophrenia was demonstrated, most notably major depression.

In an effort to reduce the retrograde memory problems that persisted for some patients after the initial recovery period post-ECT, explorations of nondominant electrode placement and alternative, more efficient, waveforms were undertaken in subsequent decades. The practice of ECT also benefited from the introduction of controlled trials methodology, which demonstrated its safety and efficacy, and from refinements made in diagnostic systems and the process of informed consent. In the 1980s and 1990s, efforts to assure uniformly high standards of practice were underway with the publication of recommendations for treatment delivery, education, and training by professional organizations in the United States, England, Scandinavia, and Canada among others.

With the current widespread use of pharmacologic agents as first-line treatments for major psychiatric disorders, ECT is now more commonly used for patients with resistance to those treatments, except in the case of life-threatening illness due to inanition, severe suicidal symptoms, or catatonia. While the failure of subconvulsive stimulation during ECT to induce remission of psychiatric illness and the effectiveness of chemical convulsive therapy suggested that the seizure was necessary and sufficient for therapeutic benefit with ECT, it is now known that there is a dose–response relationship with right unilateral ECT and that bifrontotemporal ECT may be ineffective with ultrabrief pulse widths. Work continues to explore the underlying mechanisms and biologic characteristics of effective ECT treatments with a focus on making the treatment focus on appropriate neural networks with a more efficient stimulus as a method of reducing cognitive side effects. With the growing understanding that depression is a chronic disease for many patients, more emphasis has been placed on continuation and maintenance treatments following an acute course of ECT. Work has been published demonstrating the efficacy of both psychotropics and ECT in reducing relapse post-ECT.

The utilization of ECT has diminished since the middle of the last century. ECT is relatively safe and remains the most effective treatment for major depression, and it is a rapidly effective treatment for life-threatening psychiatric conditions such as catatonia. Hence, ECT has remained in the active treatment portfolio of modern therapeutics for over 80 years. Its use has shifted from public to private institutions, and it is estimated that approximately 5–8/100,000 patients have received ECT annually over the last few decades in the United States (Table 33.20a–1).

ELECTRICAL INDUCTION OF SEIZURES

Factors in the Generation and Measurement of Electrical Stimulation for ECT

ECT is a form of brain stimulation in which induction of a seizure occurs when an applied transcranial electrical stimulus, consisting of a train of rectangular pulses that alternate in direction, creates an electrical field with a flow of current in excitable brain tissue sufficient to depolarize cell membranes of neurons synchronously. Fundamentally, the generation and behavior of the electrical stimulus have been conceptualized by Ohm's law:

$$V(\text{voltage}) = I(\text{current}) \times R(\text{resistance})$$

Voltage is the electromotor force (volts) causing current to flow; current is the rate of flow of electrons (amperes); and resistance is the relative ability to pass current (ohms). Ohm's law assumes a direct current circuit, but ECT devices function on alternating current. In this environment, it is necessary to replace resistance with the term impedance (Z). Impedance involves capacitance and inductance as well as resistance. Since biologic tissues, being nonferrous, have low inductive properties, the inductance term is usually assumed to have little relevance to impedance during ECT. Capacitance (F) is the ability to store charge (farads). Neural tissue has relatively low capacitance (10^{-12} to 10^{-10} F), and the electrode skin interface (estimated 0.4 μF), is the source of relatively more of this term.

Although it is possible to trigger a seizure with a single DC pulse of long duration, voltage and current may vary over time in the electrical stimulus as clinically used. A variety of stimulus waveforms have also been used to deliver the stimulus, including sine wave, rectified partial sine wave, brief pulse square wave, and ultrabrief pulse square waves. These different waveforms are not of equal efficiency in depolarizing neural tissue. By examining mammalian neurons, it has become evident that fast-rising current results in firing at a lower current intensity, and hence, lower dosage. The slow rise of sine wave results in accommodation and increases in the threshold for neuronal firing, estimated to be threefold. This observation has led to a preference for brief pulse waveforms that "instantly" achieve peak intensity (on the order of microseconds) over the relatively slower rising sine waveform, typically reaching peak intensity in several milliseconds.

Chronaxie, optimal current duration to depolarize human neuronal tissue is on the order of 0.1 to 0.2 ms. Furthermore, once nerves have fired, they enter a refractory period, and continued stimulation will not elicit further response. This has led to a reexamination of the need for longer duration stimulation per phase where much of the stimulus is delivered when the neuronal tissue is refractory. Even brief pulse waveforms with pulse widths on the order of 0.5 to 1.5 ms, commonly used in modern devices, may be expected to deliver excessive energy in the refractory period, although it is an order magnitude lower than with sine wave stimulation. Ultrabrief pulse waveforms, 0.25 to 0.5 ms available on modern devices, most closely approximate the chronaxie of human neuronal tissue. Finally, it has been observed that increasing the frequency of pulses is less efficient in eliciting depolarization than increasing train duration of pulses when using a brief pulse device. This phenomenon is probably also related to the complex relationship of frequency to depolarization, a U-shaped curve in primates, resulting in maximal efficiency in depolarization around 20 Hz. Duration of a pulse train has a more linear covariation with depolarization.

Table 33.20a–1.
Milestones in the History of Convulsive Therapy

1500s	Paracelsus induces seizures by administering camphor (po) to treat psychiatric illness.
1785	First published report of the use of seizure induction to treat mania, again using camphor.
1934	Von Meduna begins the modern era of convulsive therapy using intramuscular injection of camphor for catatonic schizophrenia. Camphor is soon replaced with pentylenetetrazol.
1938	Cerletti and Bini, conduct the first electrical induction of a series of seizures in a catatonic patient and produce a successful treatment response.
1940	ECT is introduced to the United States.
	A. E. Bennett develops curare for use as a muscle relaxant at ECT.
1951	Introduction of succinylcholine.
1958	First controlled study of unilateral ECT.
1960	Ottosson demonstrates that attenuation of seizure expression with an anticonvulsant agent (lidocaine) reduces the efficacy of ECT. In concert with other work suggesting that subconvulsive treatment produces only weak clinical responses, the hypothesis that seizure activity is both necessary and sufficient for efficacy is upheld.
1960s	Randomized clinical trials of the efficacy of ECT vs. medications in the treatment of depression yield response rates that are significantly higher with ECT.
	Comparisons of neuroleptics and ECT show that neuroleptic medication is superior for acute treatment, although ECT may be more effective long term.
1970	D’Elia develops what has become the most common electrode positioning for right unilateral ECT.
1976	A constant current, brief pulse ECT device, the prototype for modern devices, is developed.
1978	The American Psychiatric Association publishes the first

	Task Force Report on ECT with the aim of establishing standards for consent and the technical and clinical aspects of the conduct of ECT.
Late 1970s to Early 1980s	Randomized controlled trials demonstrate ECT is more effective than sham treatment for major depression.
1985	The National Institutes of Health/National Institute of Mental Health Consensus Conference on ECT endorses a role for the use of ECT and advocates research and national standards of practice.
1987	The belief that the seizure in itself is sufficient for clinical response is challenged by a report that the combination of dosage just above seizure threshold and right unilateral electrode placement, while producing a seizure of sufficient duration, is ineffective.
1988	Randomized controlled clinical trials of ECT vs. lithium demonstrate them to be equally effective in mania.
2000	In controlled trials, the dose/response relationship for right unilateral ECT is validated; high-dose right unilateral and bilateral ECT show equal response rates in major depression, but right unilateral electrode placement is associated with fewer adverse cognitive effects.
	Convulsive treatment is induced with magnetic stimulation by Lisanby and colleagues.
2001	The largest modern controlled trial of relapse prevention post-ECT with continuation pharmacotherapy demonstrates a significantly better outcome for combined treatment with a tricyclic antidepressant (nortriptyline) plus lithium compared to nortriptyline alone or placebo during the first 6 months post-ECT.
2006	In a large controlled trial, continuation ECT, given in a fixed schedule without concurrent psychotropic medications, is demonstrated to be effective, but a fixed schedule is only equivalent to combination lithium/nortriptyline.

2008	Ultrabrief right unilateral ECT is shown to be equivalent to brief pulse right unilateral and bilateral ECT in efficacy, but difficult to distinguish from a healthy never depressed control group in cognitive performance, including retrograde memory. In the same controlled trial, ultrabrief bilateral ECT at 150% above seizure threshold was ineffective, confirming earlier observations that the seizure itself is not sufficient for efficacy.
2013	Feasibility study of Focal Electrically Assisted Seizure Therapy published.

Once the electrical stimulus is generated, current is distributed inversely to the resistance of the tissue compartments traversed. There are three major compartments: scalp (about 200 Ω); skull (about 18,000 Ω); and brain tissue (about 200 Ω). Because current flow is greatest across the lowest resistance, it has been estimated that 80% of current is shunted through the scalp. The skull obviously provides the greatest component of resistance, and skull anatomy, for example, the position and size of sutures, skull thickness, etc., greatly influences the proportion of remaining electrical dosage that enters brain tissue. Differences in scalp and skull anatomy are thought to be a major source of the wide variation among individuals in the amount of electrical dosage required to elicit a generalized seizure or seizure threshold. These differences have been observed to be of the order of 50-fold. It has been theorized and modeled that interindividual anatomic variation in tissue layer thickness and conductivity could be compensated by varying the amplitude of the stimulus to produce a more focal and uniform electric field exposure, but the degree of adjustment required has not been determined thus far. CSF volume also affects the distribution of the electrical stimulus, with higher volume of fluid being associated with a weaker, more focal distribution and field strength.

Another influence on current shunting is interelectrode distance: The closer electrodes are placed on the skull, the more shunting occurs. It is thought that right unilateral electrode placements can result in the creation of a virtual electrode occurring in the area between the two electrodes and, hence, in reduced amounts of electrical dosage required for seizure elicitation. This increased shunting may also result in lower current density in brain tissue.

The quantity of the electric stimulus delivered has been expressed as energy (joules) traditionally, and, in the modern era, as charge (millicoulombs). Substantial evidence indicates that current density in neural tissue is the critical factor responsible for seizure production and the subsequent neurobiologic effects of the electrical stimulation. Although it is not presently possible to measure charge density directly in human neural tissue during ECT, dynamic impedance can be used to approximate charge density because of its relationship to current shunting during stimulus delivery. When electrode site preparation and positioning are standardized, anatomic factors become the major determinants of impedance. If these factors are also constant during the treatment, impedance can then reflect current density in brain tissue.

With the development of other forms of electrical and also magnetic brain stimulation, there has been revived interest in understanding and exploring the impact of electrical stimulation on brain tissue. The various elements of brain have differing electrical properties and vary markedly in excitability with myelinated axons being most excitable, and neuronal cell bodies and dendrites least. Tissue response also varies with distance from electrical source, in this case, the stimulating electrode. Although direct recording of the effects of electrical stimulation is not available for ECT, except in animal models, functional neuroimaging and computational modeling are expected to expand the current understanding of the physiology of the treatment.

Devices Used to Deliver ECT

Although constant current, constant voltage, and constant energy devices have been in use, modern devices are constant current with voltage adjusted by the device to maintain the desired current level. The range of constant current is in the order of 0.5 to 0.9 A in these devices. Dosage is manipulated by varying exposure to a fixed current (total charge). With brief pulse devices, the most commonly used constant current devices, frequency of pulses, pulse width, and duration of pulse train are parameters that can be used to vary the stimulus dosage. Because impedance varies directly with voltage, particular attention must be paid to impedance in a constant current environment. Commonly, impedance and the integrity of the electrical circuit are tested prior to stimulus delivery by passage of a low-amplitude, high-frequency test stimulus. If impedance exceeds manufacturer limits, treatment stimuli are not permitted by the device, although some devices are equipped with override features. If too high, impedance can be lowered by improving skin–electrode contact, and other parts of the circuit, for example, the cable, contacts with the electrode and device, may also need examination and adjustment. By keeping impedance within safe guidelines, local tissue damage to skin is avoided. When impedance is too low, voltage will also be very low, and may not be sufficient to drive enough current flow to brain tissue where resulting charge density may not be great enough to cause synchronous neuronal depolarization and the desired biologic effects. Low impedance is usually the result of current shunting in the scalp and is corrected by interrupting any alternative current pathway at the skin surface. For example, gel used to prepare the electrode site, perspiration, or hair products, can run together and form a continuous current pathway on the scalp, and can be corrected by removal.

Calculation of stimulus energy in joules requires information about interelectrode impedance, which is not readily available. Charge is commonly used to measure the intensity of the stimulus used in treatment with brief pulse devices. Charge is the quantity of electrons flowing through a conductor over a given time period (coulombs) and can easily be computed from the parameters of a brief pulse constant current device.

Constant voltage devices allow current to vary inversely with impedance. The typical device generates a sine wave stimulus and has a range of 70 to 170 V. With these devices, high impedance will result in low current flow, which in turn, theoretically, may be inadequate to induce sufficient charge in neuronal tissue to result in neuronal depolarization. Because the practitioner does not have access to crucial information about impedance when using a constant voltage device, and it may be difficult to assess current intensity in this setting, and judgments about the adequacy of parameters can be difficult to make. The use of these devices in the United States has become outmoded.

ECT device output in the United States has been capped at 100 J, which corresponds to a charge of 500 to 576 mC (assuming 220 Ω impedance), depending on the particular device specifications. With ultrabrief pulse width, this range is generally adequate to deliver right unilateral ECT to almost all patients. Output limitations can be addressed by using double stimulation, which provides for summation. ECT devices in the European Union and elsewhere can have an extended range up to 200 J to allow delivery of adequate dosage with brief pulse right unilateral electrode placement, which is mandated in some E.U. nations.

MECHANISMS OF ACTION

The relative inaccessibility of the central nervous system (CNS) has made understanding the pathophysiology of psychiatric diseases a continually evolving process. As a consequence, the mechanisms of action of ECT, the oldest somatic treatment currently in use in the field of psychiatry, continue to be an active area of hypothesis and research. Past and present, theories abound, and a wide range of data, particularly at the preclinical level, is available on the effects of electroconvulsive stimulation (ECS).

Proposed mechanisms have involved theories in almost every domain. These include psychological constructs; structural explanations, for example, neural plasticity; interpretations based on electrophysiology and neurophysiology; biochemical theories encompassing neurochemistry, including neuroendocrine phenomena; and other molecular rationales, including genetic and epigenetic mechanisms.

Among psychological theories, there is no evidence that fear, regression, or increased medical attention account for the efficacy or side effects of ECT. As many of the most recent advances in the field have reduced the adverse cognitive effects of ECT while maintaining efficacy, there is little reason to believe that memory loss has much mechanistic validity. Extensive reviews of the preclinical and clinical literature have refuted the assertion that brain damage occurs, let alone, accounts for ECT’s effects. Furthermore, current anesthesia practice assures that hypoxia does not occur. Sham ECT (anesthesia alone) is ineffective; hence, anesthesia is unlikely to play a role in mechanism of action.

Distinguishing the relevance of observed phenomena with ECS constitutes a major challenge in the area of mechanisms. Considerations include questions about the relevance of animal data, much of which has been derived from rodents, although there has been recent interest in primate work. This work suffers from the current lack of adequate animal models of the psychiatric syndromes for which ECT is utilized. In preclinical work, ECS is often given in a time course that does not closely follow the treatment course given to patients, that is, two to three times weekly. For example, stimulation is administered once or several times in 1 day in preclinical investigations.

ECT has a very broad spectrum of efficacy and action, as will become evident from discussions of indications for its use, of efficacy in a variety of syndromes, and of its side effects. The treatment is often studied in comparison with antidepressants or to a lesser degree other psychotropics. It is known that there is overlap in mechanistic effects, but ECT has more therapeutic effects than any studied medication. Coupled with the fact that ECT has more indications for treatment, the challenge of ascertaining critical similarities and differences is significant. Because of the perceived invasiveness of the treatment, the severity of illness among treated patients, and the necessity for anesthesia, little work is currently being done with sham ECT. There are limited data available from weaker forms of the treatment, for example, right unilateral ECT at low or modest dosage which is now known to be a less effective form of the treatment.

Biochemical Actions

There is a substantial body of work comparing ECS with psychotropic (and other) medications whose actions and mechanisms have been assayed in vitro and in vivo, most often preclinically, but also in human studies. Not surprisingly, the major areas of interest have been neurotransmitter and peptidergic systems. A primary focus has been on monoamine effects, many of which are shared by ECS in animals, ECT in humans, and psychotropics, especially antidepressants. Although it appears that both ECS and antidepressants downregulate β-adrenergic receptors, human studies of broader changes in noradrenergic pathways have been characterized by inconsistent outcomes. There are also variable data on the effects of antidepressants and ECT on serotonergic systems: Antidepressants typically downregulate 5-hydroxytryptamine receptors ($5HT_2$), whereas ECT leads to increased density of $5HT_2$ receptors (in rodents) and decreased binding (in primates). Although serotonergic transmission may be enhanced by both antidepressants and ECT, the mechanisms appear distinct. ECT is more effective than antidepressant medications, so defining what possible mechanisms are responsible for this phenomenon is of pharmaceutical as well as heuristic interest. Currently, the critical differences are not known. Both animal and clinical studies indicate increased dopaminergic functioning following ECS, particularly D1 and D3 receptor functions. Although this effect may be an underlying mechanism for ECT's therapeutic effects in Parkinson disease, it does not help clarify the underlying process for the benefits conferred by ECT on patients with schizophrenia and other psychotic illnesses, where dopaminergic antagonism, at least in some brain regions, has been presumed to be critical.

Another major area of interest has been the variety of different neurotransmitter systems, which may form the biochemical foundation for the anticonvulsant effects of ECS. Because of the efficacy of anticonvulsant medications in mania, there is also speculation that the anticonvulsant effects of ECT contribute to its efficacy in mania. Most of this work is preclinical, and indicates mixed GABAergic activity, upregulation of adenosine receptors, and blocking of anticonvulsant effects with opiate antagonists. Currently, GABAergic effects in humans are being explored neurophysiologically. It has been difficult to duplicate anticonvulsant effects of opiate antagonists in humans. The proconvulsant effects of caffeine, aminophylline, and similar compounds are observable in humans and are thought to be due at least in part to alterations in adenosine transmission, even though these agents have other biochemical effects that may also contribute. With increased interest in the exploration of the glutaminergic system in the etiology and possible treatment for depression, preclinical studies demonstrate increased glutamate levels in hippocampus after ECS in a depressive rat model. Unfortunately, it is not currently possible to conclude that alterations in any transmitter system are associated with the efficacy of ECT in any syndrome for which it is used.

Most recent preclinical research focuses on growth factors and molecular mechanisms. It appears that BDNF and NGF are both increased by a single ECS and chronic ECS, whereas neurotrophin is decreased. There is interest in linking these observations to those made of marked neural plasticity in some brain areas, for example, hippocampus, due to ECS, as will be discussed below. Work continues with a wide variety of other neuropeptides, for example, somatostatin, CCK, precursors of opiates, and thyroid hormones, etc. Other areas of interest concern the effects of ECS on second messenger systems, genetic expression, and transcription regulation. The work, focused largely on molecular phenomena related to cell proliferation—both neuronal and vascular, plasticity, and resiliency—including antiapoptotic effects, is expanding steadily, but its clinical and functional significance remains to be defined.

Hypotheses related to neuroendocrine mechanisms were generated early in the history of the use of ECT and have persisted to the present. Most hypotheses reason that stimulation of diencephalic structures, especially the hypothalamus, is involved and perhaps critical to the efficacy of the treatment. Experimental designs generated by these hypotheses have involved indirect quantification of function, specifically various peripheral neuroendocrine measures. Examples include CRH, ACTH, and cortisol, both acutely and subacutely; studies of oxytocin and vasopressin; and measures related to growth and thyroid hormones. Currently, there is no consistent evidence that acute or subacute changes in neuroendocrine factors impact efficacy or cognitive effects. Similarly, the involvement of immune system in the therapeutic effect of ECT has also been investigated. The available data suggest that a single session of ECT induces an acute, transient immune activation as measured by cellular immune function (lymphocyte subpopulations and NK cell activity) and levels of circulating cytokines, whereas repetitive ECT treatment results in long-term downregulation of immune activation. More prospective, controlled studies with larger sample sizes are needed to confirm this finding.

Neurophysiology

With advances in the area of brain imaging, neurophysiology has become a focus of interest in investigating the mechanisms of action of ECT. It is known that large increases in global cerebral blood flow (CBF) and cerebral metabolic rate (CMR) occur along with increased blood–brain barrier permeability during a generalized seizure, including those electrically induced. In the postictal period, there is functional suppression with decreases in CBF and CMR as well as varying degrees of bioelectric suppression on EEG. Changes are also topographically distributed. These reductions have been correlated with treatment outcome.

The magnitude of reductions in CBF in specific prefrontal regions is related to efficacy of ECT, and responders are more likely to exhibit postictal suppression and develop slow-wave activity on EEG than nonresponders. As techniques have been refined, the possibility of identifying specific functional networks and associating them to efficacy has improved. Related work in field modeling has yielded information concerning the way seizures are generated with various electrode placement and electrical dosing techniques as well. For example, studies comparing effective forms of bifrontotemporal, bifrontal, and right unilateral electrode placements indicate that the prefrontal cortex, particularly on the right, the anterior cingulum, and associated subcortical areas including the right medial thalamus, brainstem, and midbrain tegmentum are involved. Ineffective forms of ECT, for example, low-dose right unilateral, trigger seizures from the motor cortex, and involve the prefrontal area less. Positron emission tomography (PET) scan investigations point to these areas as well, particularly Brodmann area 25, the anterior cingulum, and the thalamus. These observations are important to clarifying which brain regions are critical to the efficacy of the treatment, as well as to understanding the dose–response relationship of electrical stimulation above seizure threshold to efficacy that has been observed for right unilateral ECT. The examination of the functional connectivity using functional MRI before and after bilateral ECT treatment revealed a significant increase in and around the left dorsolateral prefrontal cortical region (Brodmann areas 44, 45, and 46), where the average global functional connectivity was considerably decreased after ECT treatment, corresponding to the improvement in depressive symptoms. There has been expanding work using brain imaging technologies to investigate networks related to the cognitive effects of the treatment as well. Although preliminary, this work confirms the involvement of the medial temporal lobe in anterograde amnesia and points to prefrontal cortex involvement in retrograde amnesia.

Although the neurophysiologic inquiries are continuing, they are hindered by the limited localizing value and coarse resolution of currently available methods. The degree of covariance among various regions and the spatial distribution and magnitude of association are yet to be defined. There is also a need to better characterize topographies and to determine whether normalization, abnormalization, or independence of observations applies. Currently, investigational samples are small and heterogeneous as well.

Genetic and Epigenetic Mechanisms

In addition to focus on cellular level changes relevant to the antidepressant effect of ECS, advances in genomics have provided new insights about the gene expression and epigenetic changes associated with ECS. The first studies of ECS-induced gene expression were published in the early 1990s. Further studies have revealed regulation of distinct neurotrophic signaling pathways (BDNF, neuropeptide Y, vascular endothelial growth factor, fibroblast growth factor), synaptic vesicle proteins (synaptosomal-associated protein, *Syt 3 and Syn 1*), and immediate early genes (*c-fos, Egr 1, and Nrn 1*). BDNF has received extensive attention because of its involvement in the etiology of depression and response to antidepressant treatment. It has been shown that the BDNF expression in the hippocampi is elevated immediately (in the few hours) after acute ECS and decreased afterward in a temporal-dependent manner, while BDNF expression was decreased in the ventral tegmental area. The expression patterns highlight the widespread action of ECS and the spatial and temporal diversity of expression changes for each gene type.

A few studies also attempted to examine possible epigenetic mechanisms, that is, the process of modifying gene expression independent from the primary DNA sequences in the therapeutic effect of ECT. Evidence indicates a strong effect of ECS on the different epigenetic mechanisms in the rodent brain. One of the earliest studies by Tsankova et al. in 2004 reported histone modification at gene promoter regions in hippocampi of rats undergoing acute and chronic ECS in response to electrical stimulation. Increased levels of histone H4 acetylation at the promoters of the *c-fos, BDNF,* and *CREB* genes were observed after acute and chronic seizures, which, in general, corresponded with increased mRNA levels of these genes. Demethylation at the *BDNF-IX* and *FGF-IB* promoter regions, increased DNA methylation at the *Arc* promoter, and demethylation at the *c-fos* promoter region were also reported. Generalizing this work to clinical populations remains to be carried out.

Neuroplasticity

Recently, there has been increased interest in structural changes in the brain associated with psychiatric syndromes and response to treatment. This has been particularly so for microscopic changes associated with ECS, as well as antidepressant and other medications. It is observed that the delayed behavioral response to common antidepressant medications in rodents coincides with the delayed upregulation of neurogenesis, at approximately 3 weeks. Similarly, the rapid antidepressive action of electroconvulsive shock is associated with a rapid stimulation of neurogenesis, producing immature cells demonstrated to be highly excitable compared to mature neurons. Synaptic plasticity, in addition to cellular plasticity (neurogenesis), for example, sprouting of mossy fibers, alteration of cytoskeletal structure, and increased connectivity in performant pathways have been observed in animals after ECS. In addition to neurogenesis after ECS, microenvironment changes have been observed: for example, upregulation of activated microglia cells, the immune cells of the CNS, and increased proliferation of astrocytes, angiogenesis in certain layers of hippocampus, which may potentially modulate neurogenesis process after ECS. These reports have also galvanized controversy over various aspects of technical validity of the observations. It is unknown whether such changes occur clinically, and, if they do, what significance to efficacy and cognitive side effects might be discovered.

INDICATIONS

Although, historically, the first diagnostic indication for ECT was schizophrenia, practice has evolved. Approximately two-thirds of patients receiving ECT in the United States currently have major depression as the diagnostic indication for its use. The remainder has catatonia, schizophrenia spectrum disorders, mania, and a few other diagnoses, such as Parkinson disease. The clinical literature demonstrating the short-term efficacy of ECT in the major syndromes for which it is used is considerable, and includes randomized controlled trials with sham treatment or with medications as alternatives, observational data from studies involving various treatment techniques, as well as case reports/series, and surveys of expert opinion.

Beyond diagnostic indications, there are other clinical considerations commonly brought to bear in the prescription of ECT. Historically, ECT was a first-line treatment for the major psychiatric syndromes, but, with the development of psychopharmacologic treatments, use as a primary treatment has decreased, and resistance to medications has become the most common clinical indication. Nonetheless, when patients require rapid clinical response because of the severity and danger of psychiatric symptoms or medical problems resulting from psychiatric causes, ECT may be given without a prior drug trial. This is also the case when there has been prior optimal response with ECT or the patient prefers the treatment over medications (Table 33.20a–2).

Principal Indications

Major Depression. ECT is the most effective treatment for major depression currently available. It is commonly used as the standard against which other treatments, including innovative treatments such as novel forms of brain stimulation, are compared. No treatment has ever been found to be superior to ECT in the treatment of major depression in a controlled trial.

Evidence for ECT's efficacy derives from several different sources. The introduction of the treatment occurred prior to the development of clinical trials methodology in the postwar era. In the 1940s, open clinical series and case studies cited response rates of 80% to 90% with the use of ECT as a first-line treatment. Decreased chronicity of illness, decreased morbidity, and the suggestion of decreased mortality were frequently cited as benefits of ECT. From the 1950s through the 1980s, ECT was subjected to the randomized clinical trials with sham ECT and psychotropic medications as comparators. In the sham versus real ECT trials, anesthesia alone was used for comparison groups because of a concern that there were benefits from its repeated use. ECT was shown to be consistently superior, and the further use of sham conditions has been abandoned in studies of major depression. From the 1950s onward, there was also interest in the relative efficacy of antidepressants and ECT. In these reports, ECT was found to be 20% to 40% more effective than medications, and there has not been a study that found medication to be superior to ECT. Most of this work was conducted in the earlier decades of this period and is limited by the possibility that modern pharmacologic standards would dictate more aggressive dosage and duration of treatment in the medication conditions. In this type of study, adequate blinding is not possible, and concerns about bias cannot be completely dispelled even if clinical raters do not know the treatment conditions. Many of the antidepressants investigated in the past have been superceded by newer compounds, such as the specific serotonin reuptake inhibitors, and pharmacologically unique agents such as bupropion and mirtazapine. Unfortunately, there is little data to inform comparisons of ECT and modern pharmaceuticals.

Table 33.20a–2.
Indications for Use of Electroconvulsive Therapy

- Diagnostic indications
  - Principal diagnostic indications
    - Major depression, both unipolar and bipolar
    - Catatonia
  - Other diagnostic indications
    - Schizophrenia, especially treatment refractory
    - Mania, including mixed episodes
  - Less common diagnostic indications
    - Neuroleptic malignant disorder
    - Super refractory status epilepticus
- Clinical indications
  - Principal clinical factors
    - Need for rapid response required on medical or psychiatric grounds
    - Failure to respond to pharmacotherapy in the current episode
  - Other clinical factors
    - Risks of alternative treatments outweigh benefits
    - Intolerance of pharmacotherapy in the current episode
    - Patient preference

Although in an earlier era prior to modern advances in defining the phenomenology of depression, it was thought that various clinical criteria conferred a negative prognosis to the use of ECT, more recent observations have found ECT to be effective for all subtypes of major depression including unipolar and bipolar depression, melancholia, and psychotic depression. There have been suggestive data that psychotically depressed patients have a superior response to ECT, whereas there is suboptimal response with antidepressants alone and the recommended regimens of adequate doses of both an antidepressant and an antipsychotic are seldom given, perhaps due to poor tolerance of the combination. ECT may be particularly useful for psychotically depressed patients because the syndrome is often accompanied by severe symptoms and greater risk of suicide.

ECT can also be used safely in all populations of patients, including those often considered to be at special risk: the older adults, the medically ill, pregnant women, and adolescents, for whom ECT is now a labeled FDA indication. Each of these groups may require specific considerations and extra preparation and/or precautions to be taken prior to treatment. ECT has even been used to treat preadolescent children, although rarely.

Dilemmas persist among experts in the field about when to offer ECT in the course of treatment for major depression, and the speed and efficacy of ECT are often the most salient factors in selection. Severity of symptoms and refractoriness to psychotropics are the most common clinical factors for recommendation of ECT. The hierarchy of factors that need to be considered has not been resolved, but it is important to gauge the risk of not terminating an episode of depression while giving sequential trials of antidepressants along with augmentation and combination medications against the risk of the principal side effects of ECT, namely persistent retrograde memory deficits of varying significance. With recent improvements in technique, these cognitive effects have been reduced to the point where they can be difficult to detect. Even with these improvements, an acute course of ECT will often disrupt the routines of daily life because of the recovery requirements accompanying general anesthesia. Another important consideration relates to the fact that major depression is a subacute and often chronic disease with a need for continuation and maintenance treatment. For ECT, acute response is followed by the need to determine adequate continuation and maintenance treatments, most often pharmacologic, although continuation/maintenance ECT is also an option. This circumstance can also affect the timing of the choice of ECT versus pharmacology.

Finally, the response rates cited early in the history of ECT must be adjusted to the changing makeup of patient populations receiving the treatment. It appears that prior medication nonresponse within an episode, extended lengths of episode, and comorbidity with other psychiatric conditions may lower the expected response rate. Comorbidity with personality disorder, that may independently contribute to mood changes, can be especially problematic since patients with personality disorder can also suffer major depression, and it is difficult to define what phenomenology belongs to each syndrome and to determine expectations. This does not automatically mean that ECT should be withheld from these populations. Response rates to alternative treatments may be even lower, while response to ECT in antidepressant nonresponders can be expected to be 50% to 70%.

Catatonia. Catatonia is a syndrome characterized by stupor, mutism, and a variety of motor symptoms, including posturing, waxy flexibility, and catalepsy. Schizophrenia and bipolar disorder are the most frequent underlying diagnoses, but with the increased occurrence of autism in modern populations, this illness is becoming a more common diagnosis comorbid with catatonia. One of the more commonly reported uses of ECT in adolescence is for patients with developmental disorder accompanied by pharmacologically refractory dangerous behaviors thought to be on the catatonic spectrum. Currently, benzodiazepines are the primary treatment for catatonia along with a primary pharmacologic approach to the comorbid psychiatric disorder. When catatonia is resistant to benzodiazepines, ECT may be used. The data supporting this approach are largely uncontrolled, but quite positive. The syndrome of lethal catatonia is characterized by stupor or excitement, hyperthermia, autonomic dysregulation, rigidity, and changes in consciousness. ECT can be quite effective and, in fact, lifesaving.

Other Indications

Schizophrenia. Although schizophrenia is the most common diagnostic indication for ECT worldwide, there is a lack of expert consensus about its use and wide disparity in practice. Especially since the advent of atypical antipsychotic medications, pharmacologic treatment remains the first choice in the treatment of schizophrenia. ECT was introduced for use in schizophrenia, and the earliest reports, consisting of case series and comparisons with historical cohorts and nonsomatic treatments, were quite positive. As with other observations from this era, there was a lack of scientific methodology in diagnostic and outcome criteria, which would not conform to modern standards. Real versus sham ECT studies were carried out with chronic patients in the 1950s to 1960s and more acutely ill samples on neuroleptics in the 1980s. The earlier studies showed no advantage for ECT over anesthesia, but the later studies showed ECT to be superior to anesthesia alone. The source of the disparate outcomes is not clear, but in addition to differences in chronicity, the presence of neuroleptics in modern samples may be critical. Because of the positive reports of efficacy in the first decades of use, ECT was also used as the standard against which to compare newer somatic therapies, particularly neuroleptics, when they were first introduced. Although subject to the usual limitations of such early clinical trials, it soon became apparent that, at best, ECT was equivalent to neuroleptics in short-term efficacy. At this point, pharmacology superseded ECT for the treatment of schizophrenia. One observation from this era has remained intriguing and might merit further consideration. In long-term follow-up, patients who had received ECT in the first episode had superior outcomes.

In modern practice, ECT is often used as an augmentation to psychotropics for treatment-refractory psychosis, especially for those with particularly severe symptoms. In recent meta-analyses, an advantage has been shown for the combination of ECT with psychotropics, particularly clozapine. It appears that lower doses of neuroleptic are sufficient in combination treatments. Recent reports confirm the safety of using ECT and atypical antipsychotics, with the clozapine as the oldest and most reported agent. Most professional bodies issuing guidelines for the treatment of schizophrenia reserve ECT for patients who are nonresponsive or intolerant to clozapine.

In general, good prognosis patients for pharmacologic treatment are also those who do best with ECT. Evidence to support the traditional idea that the presence of affective symptoms improves the likelihood of response to ECT is inconsistent, and there is no controlled evidence concerning its use for schizoaffective patients. Uncontrolled observational evidence suggests efficacy of ECT in schizoaffective illness, but response falls short of that obtained in straightforward affective disorder and resembles response rates obtained for schizophrenia.

One last area of interest is the impact of ECT on the movement disorders resulting from neuroleptic treatment of schizophrenia. Extrapyramidal symptoms induced by neuroleptics are reversible by pharmacologic intervention, but also respond to ECT. Furthermore, there is evidence from several case series that ECT may protect against the development of tardive dyskinesia in neuroleptic-treated patients, independent of the observation that combination treatments with ECT and neuroleptic require lower doses of neuroleptic. This observation is consistent with preclinical observations of the effects of ECS on the dopaminergic system and the effects of ECT on patients with Parkinson disease.

Mania; Mixed States and Rapid Cycling. Historically, ECT was a first-line treatment for mania as well, but pharmacologic strategies, particularly lithium, anticonvulsants, and atypical neuroleptics, have become the mainstay of treatment for the manic episodes. In the modern era, the use of ECT is generally reserved for patients who are resistant or intolerant to the usual medication treatments, including those with mixed states or rapid cycling, or who have very severe symptomatology, for example, manic delirium. Compilations of the evidence for the use of ECT in mania have reported 72% to 92% response rates. The bulk of the evidence comprises uncontrolled case series, undoubtedly because of the great difficulty in conducting usual clinical trials in this population, due to uncontrolled behavior, difficulties in assuring capacity to consent, etc. Sham versus real ECT studies, with patients on neuroleptics in both conditions, demonstrated superior outcomes for ECT patients both in response rates and in lower neuroleptic requirements. Controlled retrospective comparisons have found ECT to be equivalent to lithium, and at least as efficacious as typical neuroleptics, if not more so. Prospective work demonstrated equivalence to lithium in studies where all patients received neuroleptics as well as the study treatments. One small study comparing ECT to lithium and neuroleptic in patients who failed lithium or neuroleptic found ECT to be noticeably superior to combined pharmacology. There have been no comparisons of ECT to anticonvulsants. Early work that suggested the need for increased frequency in treatment schedule and increased numbers of sessions to complete a treatment course has not been born out in modern studies, which have used standard treatment schedules.

Prospective observations and a retrospective controlled reviews have found that patients in mixed states are responsive to ECT, although increased numbers of treatments may be required compared to pure manic or depressed states. Case reports have indicated that ECT is also potentially effective in managing rapid cycling, where finding effective pharmacologic approaches can be particularly complex and difficult. Response rates are lower than for acute manic states.

Less Common Diagnostic Indications

In general, ECT treatment for other indications is supported by case material only. The use of ECT will be rare and only when standard treatments cannot be tolerated or fail.

Psychiatric. There is only very limited information about the impact of ECT on other disorders, and no evidence for clinically significant efficacy without the presence of another primary diagnostic indication. There has been interest in anxiety disorders because of the overlap in symptomatology and pharmacologic therapeutics between affective and anxiety disorders, but the only published data concern obsessive-compulsive disorder (OCD). Prospective work demonstrated acute response in OCD, but patients soon relapsed, and ECT is not recommended for this disorder. Comorbidity with post-traumatic stress disorder (PTSD) and depression has provided an opportunity to observe the effects of ECT on PTSD. A minority of patients with PTSD may be vulnerable to increased symptoms related to the syndrome, but there are also case series where PTSD improved independent of the response of depression to ECT. Patients with double depression (dysthymia and major depression) have similar response rates to those with episodic major depression alone, but are left with higher levels of mild depressive symptoms at the end of treatment, suggesting that dysthymia is more difficult to ameliorate with ECT even in the setting of comorbid major depression. The delirium that can accompany withdrawal and toxic states induced by some substances, that is, alcohol, phencyclidine, and stimulants, can be treated with ECT, but the underlying substance abuse syndrome is not significantly affected. This use of ECT is largely of theoretical interest.

Another area of concern is the issue of comorbidity with personality disorders. Here most of the work concerns cluster B disorders, especially borderline personality disorder. A secondary area of interest should be cluster A disorders because of their hypothesized overlap with axis I anxiety disorders. In general, comorbidity with one or more personality disorders is associated with poorer outcomes, especially higher relapse rates. The challenge for clinicians is to discriminate between affective symptoms that result from the personality disorder and those that constitute an ongoing affective episode. ECT is not considered to be a treatment for any personality disorder.

Neurologic. ECT has been used rarely for the treatment of several neurologic disorders, usually in situations where they are comorbid with a psychiatric disorder that is an indication for ECT. Neuroleptic malignant syndrome (NMS) is thought to be an iatrogenically induced form of lethal catatonia and is often treated with dopaminergic strategies as well as sedatives. Outcomes with ECT are equivalent to those obtained pharmacologically, but ECT has the advantage of often being a treatment for the comorbid psychiatric syndrome for which neuroleptics must be discontinued. There is evidence that NMS is less frequent with atypical antipsychotics, and the use of ECT for NMS may become less necessary as practice changes.

Open- and sham-controlled data have demonstrated that the motor symptoms of Parkinson disease, especially rigidity and bradykinesia, are lessened by ECT, particularly in the “off” phase of treatment that characterizes the phase of the disease treated with L-dopa. These effects are of 4- to 6-week duration generally, but there are reports that maintenance ECT may be helpful as well. ECT is seldom used as a primary treatment for Parkinson disease and is more frequently used to treat the comorbid depression that can occur with the disorder. The combination of ECT with levodopa/carbidopa may require decreasing medication dosage in order to stave off dyskinesia or delirium as complications of combined treatment. With the increasing use of Clozaril and other atypical neuroleptics to manage the side effects of levodopa/carbidopa, the use of ECT for Parkinson disease has diminished.

The anticonvulsant effects of ECT are well characterized, and ECT has been used in epilepsy, although effects are time limited, and ECT has no demonstrated superiority over anticonvulsant medications. When such patients are treated, including when they are treated for comorbid psychiatric conditions more commonly treated with ECT, the dosage of anticonvulsant medications is usually not changed, except when therapeutic seizures cannot be elicited. Recent reviews have suggested that ECT might be of use in intractable seizures or status epilepticus, particularly severe superrefractory status epilepticus unresponsive to pharmacologic treatment, including immunotherapy and plasma exchange. Outcomes vary with the associated underlying pathology and the degree of brain tissue damage sustained before ECT.

There are reports of lessening of pain syndromes when comorbid depression is treated with ECT. ECT has also been used to mitigate other movement disorders, for example, Tourette syndrome. Historically, there have been cases of delirium associated with both medical and psychiatric illnesses that respond to ECT, although the treatment is very, very seldom used for this reason currently.

The remainder of ECT use in neurologic syndromes is as a treatment for comorbid affective and, less commonly, psychotic syndromes. There are case reports and series of its use in poststroke depression and mood disorders accompanying dementia, mental retardation, and even head trauma and brain tumors. In all of these diagnoses, the risk of cognitive side effects of ECT can be greater, and modifications of the treatment may be needed, for example, to avoid skull defects found with trauma or to minimize the ictal blood pressure changes for patients with modest, stable brain tumors.

PATIENT MANAGEMENT

Pretreatment Evaluation

Evaluation of patients for treatment with ECT should be done as close to the first treatment session as possible. Both psychiatric and medical assessments are needed in order to conduct a risk–benefit analysis for the advisability of ECT treatment of an individual patient. In general, there are no absolute medical contraindications to ECT. Although a cochlear implant is labeled as a contraindication, ECT has been reported to be administered safely to the contralateral side of an implant, and the implants themselves were not damaged by ipsilateral ECT administration in cadavers. There is also literature on ECT use in the presence of deep brain stimulation and vagal nerve stimulation implants. Safe use requires attention to the location of ECT treatment electrodes with respect to those devices and, in fact, any implanted electrical device and consideration of temporarily turning off devices during ECT sessions. It may not be possible to administer ECT in every situation involving implanted stimulation devices.

The psychiatric component of the pretreatment evaluation is generally conducted by a practitioner privileged to administer ECT, but there are often contributions from the patient's attending psychiatrist, if different from the ECT provider. Establishing the indications for ECT will include a careful diagnosis as well as consideration of other clinical factors contributing to the recommendation for ECT, for example, severe suicidal risk. There may be local requirements and regulations for second opinions, especially in special populations such as adolescents and children.

Past treatment with ECT should be reviewed not only for response, but also to identify technical aspects and tolerance of the treatment. Knowledge of prior ECT treatments, including review of specific ECT records, will guide recommendations for the current course. Pharmacologic treatments should be evaluated for number, adequacy, tolerance, and degree of response. Psychotropic history can contribute to the indication for ECT as well as a basis for recommendations concerning post-ECT continuation treatment. Decisions regarding the adjustment of psychotropic medications pre-ECT should be based on the degree to which they may enhance response, for example, maintaining an antipsychotic; the possibility that they may interfere with ECT, for example, anticonvulsants used as psychotropics; the possibility that medications may contribute to adverse effects, for example, lithium; and the need to maintain medications for patient management while ECT takes effect.

As part of the pretreatment evaluation, there should be documentation of the target symptoms to facilitate evaluations during the treatment course and decisions concerning the termination of acute treatment. In addition to behavioral assessments, cognitive evaluation pretreatment is also critical. At a minimum, those aspects of cognitive function most likely to be affected should be documented at baseline: orientation and memory, including recall of recent and remote events. Evaluation of language and visual motor and perceptual abilities can also be valuable as well. Finally, the patient’s subjective assessment of their cognitive and memory functioning should also be documented, particularly since the predominant diagnostic indication for ECT, major depression, is often accompanied by both subjective and objective memory problems.

The medical component of the pre-ECT evaluation focuses on the patient’s ability to tolerate anesthesia as well as ECT and should be conducted by an ECT practitioner as well as an anesthetist. The general medical evaluation will be similar to that conducted for patients undergoing outpatient surgery and will focus on, although not be limited to, cardiac (e.g., congestive heart failure [CHF], symptoms of coronary artery disease), pulmonary (e.g., Chronic obstructive disease), and neurologic systems (e.g., acute stroke, increased intracranial pressure), those most likely to be impacted by ECT. The patient’s past experience with anesthesia should be elicited, as well as a family history of capacity to tolerate anesthesia. A complete list of medications, including herbal and over-the-counter medications, as well as medication allergies, is also needed. Most providers document a complete blood count and electrolytes as well as an electrocardiogram. In addition, a chest x-ray, thyroid function tests, a complete metabolic panel, and a pregnancy test in women of childbearing age may be needed. A brief dental examination for loose or missing teeth and the presence of bridges and dentures is recommended. Testing of plasma pseudocholinesterase or dibucaine number is done as indicated by patient and family history. The risk of fracture of the long bones or spine has been almost markedly diminished by the use of muscle relaxants. Hence, spinal x-rays are done as indicated by the patient’s history of skeletal injury or disease. Brain imaging is recommended when a questionable neurocognitive history, focal findings on neurologic or funduscopic examinations, or altered neurocognitive examinations are present. The basic medical evaluation should reveal whether there may be a need for further specialty consultations, testing, or labs. Many institutions involve an internist routinely, especially when conditions that can be affected by or interact with ECT, for example, diabetes, will need management during the course of treatment.

Taken as a whole, the pretreatment evaluation will result in recommendations for the modification of medications the patient may be receiving, both on a medical and a psychiatric basis; the modification of ECT technique; the modification of anesthesia technique; and the management of both psychiatric and medical conditions during the ECT course.

Consent

Written informed consent is standard in the practice of ECT and involves a discussion of the risks and benefits of the treatment with the patient and/or legally sanctioned surrogate, if the patient lacks capacity to consent. Procedures for consent are locally regulated, particularly at the state level, and familiarity with these regulations is essential. Consent can include both the anesthetic procedures and the electrical stimulation, although institutions typically provide separate consents for each of these aspects of treatment. Consent forms generally cover several different areas and can be lengthier than the type of document used for other comparable medical or surgical procedures. Descriptions of the procedure and expected benefits are detailed. Risks of the treatment including possible cognitive and medical adverse effects, including death, should be documented. The possibility of relapse and nonresponse should be included. Expected participation by or behavioral restrictions of the patient, for example, NPO for several hours before treatment, are spelled out. Alternatives to treatment, including no treatment, should be discussed. In addition to a generic description, patients should understand the individual indications and rationale for ECT. They should know who can answer any questions about the treatment that may occur during the course of ECT. It should also be clear that consent may be withdrawn during the course of treatment. The amount of information given should be tailored to each patient, recognizing that too much information can obscure the process just as too little. Guidelines and sample consent documents are available from professional organizations.

Most patients referred for ECT have the capacity to consent and can give it voluntarily. In general, capacity is assumed to be present unless there is strong evidence to the contrary. Where doubt exists as to the capacity, an independent consultation may be prudent. It is important to weigh the protection of autonomy and the opportunity to receive effective treatment in the consent process. While patients with capacity should not be coerced to receive treatment, seriously ill patients who lack capacity should not be unnecessarily obstructed from receiving it, especially when ECT is being recommended to prevent severe adverse outcomes such as increased morbidity or even death. Although regulations vary by jurisdiction, most allow for involuntary treatment with surrogate consent and/or legal review, which can include a formal judicial review. Some jurisdictions mandate not only judicial review but also review by the department of health for patients who lack capacity and object to ECT.

Surrogates should proceed through the consent process in a similar way to patients with capacity. Family members and other significant associates or companions are encouraged to become educated about ECT. Audiovisual aids and written material may be provided to patients, families, and others as indicated. Finally, it should be remembered that consent is a process throughout the course of ECT, and clinicians should maintain an open exchange about procedures, response, side effects, and prognosis. Professional organizations recommend separate consent be obtained for continuation or maintenance ECT as the indication has changed from acute treatment to relapse or recurrence prevention, and the risk–benefit assessment may have changed as well. With the increased use of tapering an acute course of ECT to continuation treatments, many hospitals have instituted consents that include a specific number of ECT sessions and duration of consent, regardless of whether they may be classified as acute or continuation ECT.

Parameters of the ECT Stimulus

Controlled trials in ECT over the past two decades have involved measuring the impact of varying aspects of ECT technique, most frequently electrode placement, pulse width, and stimulus dosing strategies, on response rates and adverse cognitive effects. Other aspects of the ECT stimulus include the direction and amplitude of the current and pulse frequency. Research from a prior era had led to a belief that seizure elicitation was necessary and sufficient for efficacy because subconvulsive stimuli were associated with lower response rates in several studies. When attenuation of electrically induced seizures with lidocaine was also associated with reduced efficacy, adequate seizure duration was also postulated to be necessary for therapeutic response. These tenets have been revised in light of observations from modern studies, and current practice has been directly impacted.

A series of studies since the 1980s demonstrated that, depending on the combination of electrode placement and stimulus dosage, seizures could vary in eliciting clinical response from 20% to 70%. Recent studies utilizing an ultrabrief pulse stimulus configured the waveform in a more physiologic way in order to minimize excess electrical dosage, similar to the substitution of brief pulse waveform for the original sine waveform. Right unilateral electrode placements were particularly affected by dosage, and a dose–response relationship exists up to a stimulus intensity of 8 to 12 times the seizure threshold. At electrical dosage six times the seizure threshold, right unilateral ECT is equivalent to bilateral ECT in clinical efficacy but maintains an advantage in producing fewer adverse cognitive effects. For electrical dosage above six times the threshold, the advantage in acute cognitive effects may be eroded, but there is evidence that an advantage in long-term cognitive effects remains. These findings make dosage relations with seizure threshold particularly critical for right unilateral ECT. Ultrabrief right unilateral ECT at six times seizure threshold has been shown to be equally effective to both brief pulse bilateral ECT and brief pulse right unilateral ECT; ultrabrief bilateral ECT at 2.5 times seizure threshold was an ineffective treatment in at least one randomized trial, and brief pulse waveform is recommended for bilateral ECT. Manipulation of the waveform in this manner had even more powerful effects on cognitive outcomes than had electrode placement, with results for ultrabrief right unilateral ECT statistically indistinguishable from those obtained in cognitive testing of age-, gender-, and IQ-matched medically and psychiatrically healthy controls on measures of retrograde amnesia. Combined with the results of neurophysiologic and brain imaging studies of the effects of ECT, the clinical impact of the interaction of electrode placement and dosage also suggests that the antidepressant effects of ECT are dependent on the anatomic specificity of the effects of current density rather than on seizure elicitation alone. It was also found that the speed of clinical response can be enhanced as stimulus intensity was increased above the seizure threshold for both unilateral and bilateral electrode placements.

Although there has long been a theoretical interest in greater localization of the effects produced by ECS in brain tissue, the neurophysiologic and clinical findings related to the interaction of electrode placement and stimulus intensity have rekindled interest in concentrating current density in prefrontal areas by manipulating electrode placement.

Electrode Placement. Historically, most practitioners have used bifrontotemporal electrode placement because of its reliability in producing efficacy and its ease of use. This electrode placement is also associated with more short- and long-term adverse cognitive effects, and is more likely to produce delirium, which may require interrupting a course of ECT and perhaps even terminating it before optimal therapeutic effects have been obtained. Hence, when bifrontotemporal ECT is used, attention should be paid to restricting dosage to a moderately suprathreshold to attenuate adverse cognitive effects as much as possible. It should be emphasized that the combination of ultrabrief pulse and bifrontotemporal electrode placement has not been demonstrated to be consistently effective. Treatment with bilateral electrode placements, particularly bifrontal configuration, is more likely to manifest EEG seizure without motor seizure, and EEG monitoring is particularly useful in detecting the occurrence of a seizure at treatment.

Newer electrode placements include bifrontal configuration and asymmetric placements. There are limitations to these strategies, imposed by the fact that the high impedance of the skull and scalp causes spreading of the electrical stimulus and restricts possibilities for localization of the stimulus. Bifrontal electrode placement, with positioning far enough laterally to minimize interference with impedance relations, has been investigated and there have been several demonstrations that bifrontal electrode placements are equally effective to bifrontotemporal and adequately dosed right unilateral electrode configurations. Evidence of advantages in sparing of cognitive effects is preliminary, and adequately powered investigations with more extensive and sensitive cognitive batteries are needed. Seizure threshold is likely to be relatively higher with bifrontal ECT.

The relatively better cognitive side-effect profile of right unilateral ECT should encourage wider utilization now that the efficacy of this electrode placement can be assured with adequate dosing strategies. In contrast to bilateral ECT, a dosage closer to 500% above the seizure threshold for right unilateral ECT is more likely to assure efficacy. ECT devices in the United States are restricted to an output in the range of 504 to 576 mC. Approximately 90% of patients have seizure thresholds that can accommodate optimal dosing with brief pulse right unilateral ECT, and the combination of right unilateral electrode placement with ultrabrief pulse width extends the range of U.S. devices so that most patients can be treated within these constraints. Maximizing interelectrode distance by using the d’Elia placement for right unilateral ECT may also be optimal. Many other right unilateral placements have been described, but there is little work to support their use (Fig. 33.20a–1).

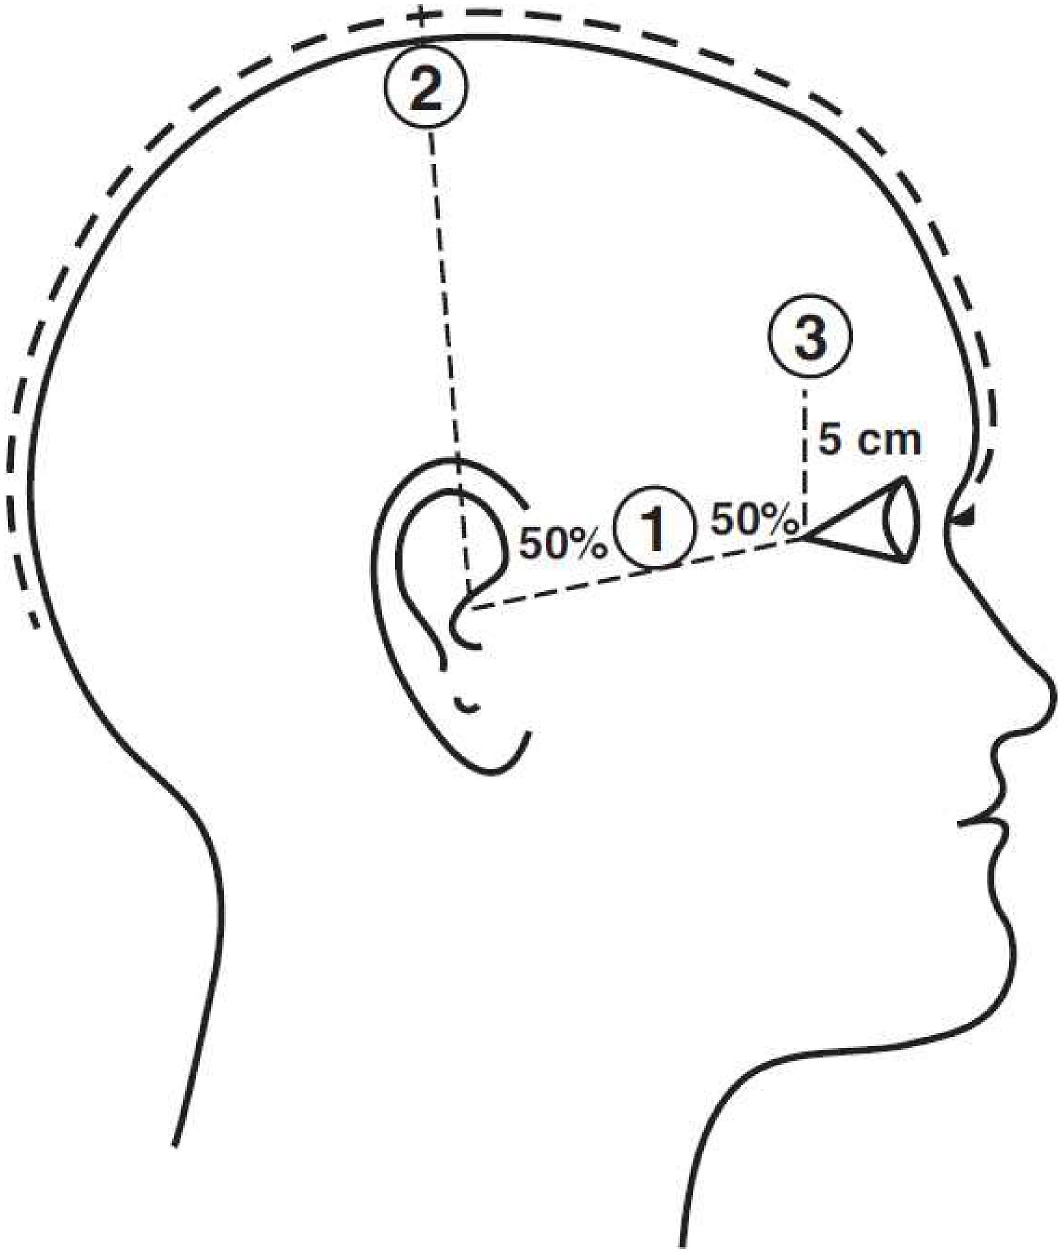

FIGURE 33.20a–1. Electrode placements. Position no. 1 represents the frontotemporal position, used for both electrodes, one on each side of the head, in conducting traditional bilateral ECT. For right unilateral ECT, one electrode will be in the right frontotemporal position, and the other will be just to the right of the vertex at position no. 2. Position no. 3 represents the frontal placement, used for both electrodes in conducting bifrontal ECT.

There has been some concern that left-handed patients may require different electrode placement from right-handed patients, especially if a unilateral placement is desired. There is evidence for independent lateralization of affect, with the right hemisphere involved in sustaining depressed mood regardless of handedness. In addition, no differences in efficacy have been found to be related to handedness when examined in studies. Because of limited indications that affective function and efficacy of ECT are associated with handedness, it is not generally used to guide the choice of electrode placement.

Stimulus Waveform. The original ECT devices used in the 1930s generated the electrical stimulus as a sine wave, with a rather wide pulse width, approximately 8.33 ms (60 Hz). Modification of the waveform to a bipolar rectangular pulse, 0.5 to 2.0 ms wide, represented an advance: diminishing nonessential electrical dose, dramatically reducing adverse cognitive effects, but preserving efficacy. Modern ECT devices retain this capability. However, neurophysiologic observations suggest that the optimal pulse width for neuronal depolarization is actually in the range of 0.1 to 0.2 ms. Thus, the brief pulse width is inefficient and delivers unnecessary stimulation. While reductions of pulse width to this extent may not be practical with the current engineering of ECT devices, several reports, including randomized controlled trial evidence, employing a pulse width of 0.25 to 0.3 ms (known as “ultrabrief”), have demonstrated that right unilateral ECT, typically at six times seizure threshold, is equivalent in efficacy to both right unilateral and bilateral ECT using brief pulse widths.

In one report, patients treated with the ultrabrief pulse width showed significantly less impairment in acute, subacute, and long-term cognitive side effects of anterograde and retrograde memory than patients receiving standard pulse width stimulation for both right unilateral and bifrontotemporal ECT. In fact, those who received ultrabrief right unilateral ECT did not deteriorate in any cognitive measure relative to pre-ECT performance. A smaller randomized trial confirmed the equivalent efficacy of ultrabrief and brief pulse right unilateral ECT. In effectiveness, open-label prospective and retrospective studies, findings have been more mixed, although predominantly positive for the efficacy of ultrabrief right unilateral ECT, but the lower quality of these designs must be factored into judging the outcomes presented. The possibility of differences in speed of response among electrode placements has been raised but not resolved. It is likely that there are a very small minority of patients who require specific electrode placements. for example, bifrontotemporal, and pulse widths, for example, brief pulse. It is not recommended that pulse wide exceeds 1 ms in modern ECT.

Seizure Threshold and Dosing. As indicated above, the intensity of the electrical stimulus, that is, the degree to which electrical stimulus exceeds the seizure threshold, affects the efficacy of right unilateral ECT, the speed of clinical response, and the cognitive side effects produced, regardless of electrode placement. The effects are in the same direction for each of these domains: the higher the stimulus dosage above the seizure threshold, the better the efficacy of right unilateral ECT up to 8 to 12 times the seizure threshold, the quicker the clinical response by one or two treatments over a course, and the greater the cognitive side effects. These observations have led to the development of dosing methods to refine stimulus intensity.

Strategies for determining stimulus dose include dosing based on empirical determination of seizure threshold (titration), formula-based dosing, and fixed dosing. Empirical titration involves an approximation of seizure threshold in the first treatment session, followed by a calculation of optimal dosage based on the results obtained. The first electrical stimulus in the titration is set low enough that a seizure results in only a minority of patients. Restimulations at intervals of 30 to 60 seconds are given in the same session using progressively greater amounts of charge until a seizure is produced. The stimulus intensity estimated on this basis (seizure threshold) is then generally used to compute dosage for the ensuing ECT sessions.

The dosage at which a seizure is elicited (seizure threshold) has been found to vary at least 50-fold in patients undergoing ECT. Because of the wide variation in seizure threshold, dosing based on empirical titration is thought to be the most precise method of stimulus determination. Furthermore, it is safe for most patients when conducted with adequate physiologic monitoring and the use of anticholinergic agents as appropriate to prevent the brief periods of bradycardia that may accompany subconvulsive stimulation. In controlled trials where the dosing was based on empirical titration, patients benefited clinically beginning with the first treatment session even though dosage was given near the threshold, a theoretical concern with right unilateral electrode placement. The seizure threshold, as empirically determined, increases by 20% to 100% over the course of ECT but returns to levels observed in the first treatment session within a week of ending treatment. Because of increases in seizure threshold over the course, retitration and dose adjustment may be needed if clinical symptoms plateau.

Formula-based dosing uses factors known to influence seizure threshold, such as age, electrode placement, stimulus pulse width, gender, and concomitant medications including anesthetics, to estimate adequate stimulus intensity. Seizure threshold is generally higher in men than women, with bilateral electrode placement than with unilateral electrode placement, and with increasing age. It is currently unresolved whether bifrontal electrode placement results in differences in seizure threshold when compared with bifrontotemporal placement. The basis for these observations has not been extensively investigated. The simplest formulae use age alone, but even the most detailed and elaborate formula can only account for about 40% of the variance in seizure threshold observed in patients. Hence, there has been limited success obtaining precision in seizure threshold approximation and dosing using formulae.

Fixed dosing occurs when the same dosage of electrical stimulus is applied to all patients receiving ECT. It is obviously the easiest technically and may maximize the chances of clinical response, especially for right unilateral electrode placement. Unfortunately, this dosing strategy can cause patients with the lowest seizure thresholds to receive up to 20 times an adequate electrical stimulus, especially with bilateral electrode placement. For low-threshold patients, fixed dosing enhances the possibility of increased adverse cognitive side effects. If fixed dosing is used with right unilateral electrode placement, the expected benefit in adverse cognitive effects could be lost. It is felt that fixed dosing may be appropriate only for patients with such serious medical conditions that even one subconvulsive stimulus, as is still a possibility even with formula-based dosing, must be assiduously avoided. Fixed dosing at the maximum output of the device should be avoided.

Seizure threshold and subsequent dosage determination can also be influenced by which stimulus parameters are adjusted. Comparisons of adjusting frequency versus stimulus train duration on brief pulse devices have indicated that longer duration is more efficient in eliciting seizures than increased frequency, although the effect sizes are small. Recent work has also shown that frequency does not exhibit a linear function in the depolarization, an observation that complicates understanding this relationship. Efficiency in seizure elicitation can also be optimized by using narrower pulse widths in setting the parameters on brief pulse devices. This strategy has the additional effect of extending the range of devices which are capped in stimulus output. There has been recent interest in optimizing pulse amplitude as well with initial indications that further efficiencies may be obtained. Use of unidirectional stimuli is under investigation.

Anesthesia and Treatment Procedures

Since ECT is given under brief general anesthesia, the treatment is usually performed in a specific treatment area that generally meets standards for the performance of day surgery, including the capacity to manage medical emergencies and to recover patients postictally. The staffing commonly consists of a psychiatrist privileged to administer ECT, an anesthetist, and one or more nursing personnel. Although the anesthetist maintains responsibility for anesthesia procedures, particularly airway management, the treatment procedures are conducted collaboratively.

Before anesthesia is induced, appropriate physiologic monitoring is instituted and continued until the patient is adequately recovered. Cardiac monitoring and pulse oximetry are standard; monitoring end-tidal carbon dioxide is also standard at many institutions. Automated noninvasive blood pressure monitoring, set at a short frequency, is common. Monitoring of seizure activity consists of observing both motor and EEG seizure duration. Motor seizure duration can be determined optimally using the “cuff method.” A blood pressure cuff is applied to the forearm or just above the ankle and inflated to a level above the anticipated maximum systolic pressure (>250 mmHg) to prevent anesthetics from affecting muscle contraction in the distal limb. Motor movements resulting from seizure induction can then be directly observed. The cuff should be ipsilateral to electrode placement for unilateral ECT. Ictal movements may continue longer in the face and neck. Use of the cuff method may not be appropriate for patients with severe peripheral vascular conditions, especially in the lower limbs. ECT devices have incorporated technology to allow at least 2-lead EEG monitoring with a frontal–mastoid montage preferred. Care must be taken to prepare EEG sites adequately and to take into account artifacts, for example, heartbeat and movement. Current FDA labeling requires EEG monitoring.

Oxygenation is provided using 100% O_2 at 15 to 20 breaths/minute via mask, and administered under positive pressure when respirations have stopped secondary to anesthesia medications, except during electrical stimulation. Respiratory support is discontinued when there is return of spontaneous respiration adequate to maintain clinically acceptable hemoglobin saturation on room air. Preoxygenation begins 2 to 5 minutes prior to induction and even earlier in the sequence of treatment procedures when medical conditions such as obesity or pulmonary disease pose a risk to respiratory function. In rare circumstances, such as third trimester pregnancy or anatomic airway anomalies, patients may be intubated.

There is variation in the use of anesthetic medications. Anticholinergic medications such as atropine and glycopyrrolate are usually unnecessary but may be used to dry secretions that may interfere with respiration under anesthesia and to decrease the vagally mediated bradycardia and asystole. The cardiac effects of anticholinergic agents are most useful in the following clinical situations: during seizure threshold titration when subconvulsive stimuli will not be accompanied by compensatory catecholaminergic output for every stimulation; in the presence of agents that promote bradycardia, for example, β-blockers; and when cardiac conditions characterized by some degree of the electrical blockade are pre-existent. Anticholinergic agents may be contraindicated when they might provoke pre-existing arrhythmias or threaten cardiac compensation through increases in workload from higher heart rates. Although glycopyrrolate does not cross the blood–brain barrier under normal circumstances and could have an advantage over atropine, controlled comparisons with atropine have not detected differences in cognitive or cardiac adverse effects or postictal nausea, perhaps because ECT disrupts the blood–brain barrier and diminishes this advantage.

Ultrabrief general anesthetics are used to induce unconsciousness while muscle relaxants are in effect and during seizure elicitation. Methohexital, a short-acting barbiturate, has been the preferred agent in the United States, due to near-ideal kinetics and only moderate anticonvulsant effects. Alternative anesthetics include short-acting agents from a variety of classes, including propofol, etomidate, ketamine, and short-acting opiates remifentanil and alfentanil. Propofol reduces hemodynamic changes accompanying ECT and typically produces a rapid, smooth recovery. Its antiemetic properties can be useful when patients develop nausea or vomiting. This agent also attenuates seizure duration, but studies comparing it to more standard agents have not detected differences in clinical efficacy or cognitive recovery. Agents that attenuate seizure duration, generally are associated with slightly shorter emergence and recovery although a recent review concluded that the differences while statistically significant may not be of sufficient magnitude to affect the choice of agent. Etomidate does not affect seizure threshold and is associated with fewer cardiac side effects, although recovery may be longer than with other agents. Etomidate can also produce myoclonus, and repeated use in animals has been associated with reductions in adrenal function, although no clinically relevant adrenal suppression has been associated with the intermittent dosing schedule associated with its use during ECT. Ketamine, an NMDA receptor antagonist has been associated with longer seizures in animals given ECS. With the potential involvement of the glutamatergic system in the etiology of major depression and schizophrenia, as well as the potent independent antidepressant effect of ketamine, and the theoretically neuroprotective effect of ketamine against cognitive impairment associated with ECT, the use of ketamine in ECT treatment has resurged. To date, studies do not support a synergistic antidepressant effect or mitigation of cognitive side effects of ketamine and ECT. Unfortunately, ketamine can result in hallucination and unusual states of consciousness as well as increases in heart rate and blood pressure. In general, both etomidate and ketamine have been reserved as alternative or adjunctive agents for situations where seizure elicitation is difficult. Greater attention to adequate dosing of these anesthetic agents has become increasingly important as the increased use of cognitively sparing techniques, such as ultrabrief right unilateral ECT have been accompanied by reports of patients regaining awareness and remembering the effects of succinylcholine before full respiratory capacity returns to baseline. Numerous reports have explored using short-acting opioids, either alone or in combination with standard agents. In combination, less of the standard agent is required and seizure durations can be longer; apnea may be longer than with other anesthetics.

Before the development of muscle relaxants, musculoskeletal injury, particularly fracture of the long bones or vertebrae, was not uncommon, as it is today. Muscle relaxants are part of the standard of care with ECT. Curare was developed to reduce the tonic–clonic movements produced by the electrical induction of a generalized seizure, but its use has been superseded by succinylcholine, a depolarizing agent with rapid onset and brief duration. Before administration, the airway must be secure, and unconsciousness achieved. Although modification of movement is the usual goal of using muscle relaxants, complete paralysis may be desirable when there is a history of skeletal disease, such as osteoporosis or a recent fracture. Myalgia can be a side effect of succinylcholine. The standard treatment of these myalgias, which are often present in only the first few treatments, is the use of common analgesics. If the use of succinylcholine is contraindicated, as in pseudocholinesterase deficiency, neuromuscular disease, prolonged immobilization, or risk of hyperkalemia, then nondepolarizing agents can be employed, although very low–dose succinylcholine is sometimes also an option. Agents available in the U.S. market, for example, rocuronium, are rather longer acting, even when the reversal is produced with an agent such as sugammadex.

Although complications at ECT have involved the cardiovascular system most commonly, the routine use of agents, such as β-blockers, which reduce the increases in hemodynamic activity that accompany ECT, is not recommended. Controlled studies of routine use do not demonstrate advantages for active intervention, perhaps because the patients who benefit are a minority of the entire population of ECT recipients, most of whom easily tolerate the observed increases in heart rate and blood pressure for a few minutes. There has also been some concern that the hypermetabolic cerebral state induced by the treatment requires a corresponding increase in cardiovascular functional level to maintain adequate oxygenation and nutrient supply to the CNS. The conservative position is to restrict the use of pharmacologic intervention to those conditions where the need is unambiguous, for example, aneurysm, sustained hypertension, and/or tachycardia.

Because the application of the electrical stimulus directly stimulates contraction of the jaw muscles, a flexible foam or rubber bite block is placed in the mouth just before the delivery of the electrical stimulus to protect the teeth and oral soft tissues. Stimulus duration is typically only a few seconds.

Patients are recovered with monitoring of cardiovascular and respiratory functioning until physiologically stable. If not awake and oriented at that time, further recovery is needed until the patient is alert and reoriented. Patients with medical comorbidities, that is, morbid obesity may require a lengthy period of recovery supported with prolonged oxygen supplementation. Many facilities require that the patient be fully ambulatory before leaving the treatment and recovery areas. Bed rest may be needed for a period of time. Side effects, such as headache and nausea, are monitored and treated as needed. Headache frequently responds to analgesics, especially COX inhibitors; patients with migraine may require more specific antimigraine treatments. Postictal delirium with agitation, disorientation, and lack of full consciousness, occurs in a minority of patients. Decreasing environmental stimulation and securing protection may be adequate management, but not infrequently, patients will require intravenous (IV) pharmacologic intervention with sedatives and prophylaxis at subsequent treatments.

ECT is considered an urgent, not an elective, procedure, both for acute and continuation and maintenance courses. In the COVID-19 era, patient screening for both urgency and infection status, adequate personal protective equipment for staff, and modifications of anesthesia, an aerosolizing process, should be implemented. Suggested modifications include maximal preinduction oxygenation, using bag-mask ventilation only when desaturation begins, viral filters in anesthesia circuits, limiting use of AMBU, and disinfection of nose and mouth.

During a treatment session, seizure duration is monitored for motor and EEG duration, with seizure duration commonly less than 1 minute. Motor duration is measured by observation of a cuffed limb with the cuff applied prior to muscle relaxant, and of the entire body as well; EEG is measured by application of one or two channel front-mastoid EEG leads prior to induction of anesthesia with visual and possibly auditory output on the ECT device. The relationship of duration to efficacy is tenuous at best, and it is clear that duration alone is insufficient to insure clinical adequacy. Seizures of less than 15 seconds can occur close to seizure threshold and are often considered abortive. Seizures of similar duration can also be observed in older adults, late in a treatment course, and with markedly suprathreshold dosage, but such short-duration seizures may not be associated with lack of adequacy. These circumstances highlight the usefulness of empirical titration techniques to inform the practitioner more exactly about seizure threshold and dosage, and to guide what actions, if any, to take when short seizures occur. Hyperventilation pre-ECT, decreasing dose of methohexital or propofol and substituting short-acting opiates (remifentanil) for part of the dose, switching anesthetic to etomidate or ketamine, and reversal of benzodiazepines with flumazenil are strategies used to lengthening seizure duration. Seizures longer than 3 minutes, with either motor or EEG monitoring, are considered prolonged and should be actively controlled using IV anticonvulsants, such as the short-acting barbiturate used to induce anesthesia or benzodiazepines. The occurrence of long-duration seizures is unusual, except in the youngest patients, and the cause of such long duration should be investigated, especially if it was not easily terminated.

Treatment Course

Typically, ECT is given two to three times weekly on nonconsecutive days. The latter frequency is common in the United States. Twice-weekly treatment is equally effective compared to thrice-weekly treatment, can take longer to reach efficacy, and is associated with fewer acute cognitive side effects. Other frequencies of treatment are more problematic. Daily treatment is seldom done now, but, at one time, was believed to speed efficacy dramatically and was used in the most urgent situations, for example, severe mania. This treatment schedule was also characterized by a risk of prolonged severe cognitive side effects, especially when a course known as regressive ECT was used. In addition to being logistically difficult to obtain in many places, the risks appear to outweigh the benefits, and daily treatment is no longer advised. Another approach to increasing frequency was eliciting more than one generalized seizure per session under continuous anesthesia, known as multiple-monitored ECT (MMECT). Similar to daily ECT, the goal was to accelerate clinical response with the additional advantage of decreasing the number of times anesthesia is delivered. Although there have been both reports of uncontrolled observations and one controlled trial concerning MMECT, the literature is clear that severe adverse events accompany this treatment approach with only modest gains in efficiency of response. Of most concern are reports of cardiovascular morbidity and mortality, as well as serious adverse cognitive effects including prolonged confusion. Although there may be a place for the use of MMECT, it is only in extremely unusual circumstances, for example, intractable seizures, and should be restricted to double stimuli/session. At the other end of frequency, once-weekly ECT is associated with weaker clinical response and more suitable for continuation ECT schedules where the goal is to maintain a patient’s status as responder or remitter—as opposed to acute treatment, which is used to induce response.

The number of treatment sessions in a course of ECT should be individualized, as patients vary in this requirement from a few sessions to more than 15, especially when changes in treatment technique have been made. The course length cannot be predicted, although the average is from 6 to 12 sessions. Fixed course lengths are not appropriate for these reasons. Patients should be evaluated every one to two treatments for clinical response and adverse side effects, particularly cognitive effects. These assessments are best done between treatment days when the acute effects of anesthesia and ECT will interfere less with evaluation. Acute treatment should end when there is remission of target symptoms or when further improvement has not occurred over two to three sessions with optimal technique.

When response is inadequate, modifications can be considered. Such modifications can include intensification of stimulus energy by increasing charge through manipulations of the various parameters of the stimulus or by changing electrode placement. Seizure threshold increases over the course of treatment, so higher stimulus intensity may be useful later in a treatment course if response is inadequate, particularly if response was more robust earlier in the course but waned. If any medications with anticonvulsant properties, including barbiturate anesthetics or propofol, are being used, discontinuation or decreasing dosage should be evaluated, particularly when the patient has high seizure threshold. At least 10 treatments with optimal electrode placement and dosing should be given before nonresponse is declared. When course length exceeds 15 to 20 sessions, especially with modifications of technique, reconsideration of the use of ECT, with careful balancing of the risk of an unresolved episode of illness against the risk of accumulating adverse effects, should be undertaken. Additional consultation, with reassessment of primary and comorbid diagnoses, may be advisable.

ECT is the only treatment for major psychiatric syndromes that is discontinued when remission occurs. Hence it is not surprising that a significant proportion of patients who relapse do so within the first few weeks of termination of ECT and then require further ECT. Often additional ECT is given along with medications that will be used for continuation and maintenance of remission. Although not yet examined in a controlled trial, tapering the termination of ECT by decreasing the frequency of sessions while medications are stabilized and producing their effects may be a more effective strategy for relapse prevention.

Continuation Treatment

Continuation treatment, that is, treatment for 6 months beyond remission of an acute episode of illness to prevent relapse, is standard practice for the major syndromes that are somatically treated. It is recommended and routine post-ECT as well. Populations that receive ECT are particularly likely to be characterized by risk factors for relapse: medication resistance and the presence of psychotic features. At least half and upward of 85% of ECT responders in some samples will relapse without continuation treatment particularly in the first several weeks post treatment. Aggressive continuation treatment should be initiated as soon as remission is evident, although initiation of pharmacology during the ECT course itself has not been shown to be of additional benefit for depression.

Continuation treatment with medications is the predominant practice post-ECT. This has been based on studies conducted in the 1960s in Britain and on clinical experience. The class of agent advised matched that used in the absence of ECT: antidepressants for unipolar depression, antidepressants and mood stabilizers for bipolar depression, mood stabilizers with or without antipsychotics for mania, and antipsychotics for schizophrenia. Studies in the 1970s found little support for the use of lithium alone as relapse prevention following depression, but some support for lithium as maintenance treatment after 6 months of remission to prevent recurrence once remission is firmly established. The first randomized prospective controlled study of continuation treatment post-ECT in unipolar patients confirmed substantial relapse rates on placebo (84%), but only moderate improvement in relapse rate on the antidepressant nortriptyline alone (60%). The relapse rate in unipolar depression was significantly reduced in this study by the addition of lithium to nortriptyline (39%) with most of the relapse in this arm of the study occurred in the first 5 weeks. Randomization had been stratified by medication resistance and (mood congruent) psychosis, but mood congruent psychotic patients did not relapse more frequently. Medication dosage was in the range used for acute treatment. A prospective trial of combination antidepressant and antipsychotic continuation treatment post-ECT did not find an advantage for combination treatment over antidepressant alone in an older adult population, and the combination treatment was found to be associated with greater frequency of side effects. A recent randomized controlled trial found no advantage for beginning nortriptyline or venlafaxine during the course of ECT in preventing relapse. Observations of community practice post-ECT yield relapse rates similar to those found in the RCT assignments using antidepressants alone. Little is known about the use of second- and third-generation agents or anticonvulsant mood stabilizers in relapse prevention, although preliminary evidence suggests that the combination of lithium and antidepressant is more effective than other medication combinations in maintaining remission. There is also preliminary work indicating that combining medications with continuation ECT or cognitive therapy is more useful than monotherapy. There are preliminary studies suggesting that relapse prevention is more effective when using a class of antidepressants that was not shown ineffective prior to ECT treatment. Modern practice suggests sparing use of antidepressants in bipolar patients, but in continuation treatment post-ECT, antiepileptic drugs or antipsychotics have not been shown to be all that effective in preventing relapse to bipolar depression. Little work in pharmacologic relapse prevention post-ECT for any other diagnosis than depression has been done in the modern era.

ECT was introduced before the psychopharmacologic era; thus, administering ECT after an index episode was not uncommon early in the history of ECT. With ECT populations becoming increasingly medication resistant and various pharmacologic strategies still characterized by relapse rates in the range of 40%, there is renewed interest in continuation ECT for patients who relapse on continuation pharmacology. The first randomized controlled comparison of continuation ECT in a fixed schedule with the combination of nortriptyline and lithium did not show an advantage for ECT and confirmed relapse rates observed in prior studies; relapse escalated when the schedule of administration dropped below once weekly. Other prospective data have confirmed these observations. Recent prospective, controlled, nonrandomized data as well as post hoc analyses from the RCT support the practice of tapering ECT after an acute course, combining ECT and pharmacology as continuation treatments, and using a symptom-driven, flexible schedule of ECT administration to improve relapse prevention. A recently completed RCT has confirmed this practice.

Recommendations from professional organizations have guided various aspects of the practice of continuation ECT although these bodies use differing thresholds for evidence when recommending strategies, a circumstance most notable when the National Institute for Health and

Clinical Excellence in the United Kingdom issued guidelines in conflict with the Royal College of Psychiatrists as well as other professional bodies in the Commonwealth and globally. Suitable patients for continuation/maintenance ECT should have recurrent illness, demonstrated response to ECT, intolerance of or relapse on continuation medications, and ability to comply with continuation ECT protocols, particularly behavioral prescriptions, such as fasting prior to the procedure, and restrictions, such as refraining from important decision making for a period of time following each treatment. In general, continuation ECT utilizes the electrode placement and dosage which produced remission. A taper of ECT from the acute phase to continuation phase has become common. Treatment frequency is gradually extended between treatment sessions, as tolerated, to monthly or even less often. It is thought that if patients remain well 2 months or more, they are out of episode, and the discontinuation of continuation ECT can be entertained. Continuation ECT is almost always given in an outpatient setting. Cognitive functioning should be monitored as well as the status of psychiatric symptoms and medical fitness for each session. There has been one promising but uncontrolled pilot study of the use of cognitive behavioral therapy to augment somatic continuation treatments post-ECT.

Maintenance treatments are those given beyond the 6-month continuation treatment period and the purpose of these treatments is prevention of recurrence. Because patients receiving ECT in current practice are almost always suffering from highly recurrent illness, maintenance treatment can be entertained for most ECT responders who do not relapse with continuation treatments. There are now several controlled observations of the use of maintenance ECT up to 4 years with positive outcomes in relapse prevention for depression. Japanese investigators have published a case series on the use of ECT as a maintenance strategy for treatment-resistant schizophreniform and catatonic illness. Individual decisions about maintenance treatment will be informed by the number, frequency, and intensity of prior episodes; the ability to tolerate continued treatment; the ability to comply with treatment; the experience when attempts to taper treatment are made; and patient preference. Again the standard will be maintenance medications. Maintenance ECT is also available, especially for those patients undergoing continuation ECT when medications have proven inadequate. Maintenance ECT is similar in many aspects to continuation ECT, and it is performed at the longest intervals to sustain remission. There is no evidence that a lifetime maximum number of ECT applies.

INTERACTIONS OF MEDICATIONS AND ECT

ECT can interact with medications given for psychiatric as well as medical conditions. As such, patients' medication regimen should be reviewed for risk and benefit during an ECT course to determine whether it is necessary to make changes. Changes can include tapering, withdrawing, augmenting, or adjusting the timing of administration of medications. Some psychotropics and many drugs for medical indications are continued. Medications that are already a part of the patient's treatment regimen and are expected to mitigate physiologic changes that accompany ECT or protect against adverse reactions to ECT or anesthesia are often given the morning of treatment. Examples are antihypertensives, antireflux agents, inhalers for pulmonary conditions, and steroids, although anesthetists may wish to substitute IV steroids for oral steroids pre-ECT. It appears that stress doses of steroids may not be necessary at ECT. Lidocaine and its analogs can interfere with seizure induction and should be withheld. Other medications that should be held until after recovery are diuretics, hypoglycemics, including insulin, depending on an individual evaluation of the patient's needs, and long-acting cholinesterase inhibitors for glaucoma that may interfere with anesthesia recovery.

Medications that can result in severe adverse reactions include theophylline and lithium. Theophylline is a member of a class of agents that are known to increase seizure duration, and theophylline can result in status epilepticus, even at therapeutic levels, when administered during an ECT course. In fact, caffeine, a short-acting member of the same class of medications as theophylline, had been used to increase seizure duration when seizure length was thought to be a critical parameter to ECT efficacy. Inhaled bronchodilators and steroids, as well as other oral and inhaled agents, have replaced theophylline in modern pulmonary practice to a great extent. If theophylline is part of the therapeutic regimen and ECT is undertaken, consultation to evaluate the possibility of a substitute regimen is generally sought. Lithium combined with ECT has been shown to result in confusional states, serotonin syndrome, and prolonged and/or focal seizures. Although it is not neurotoxic in all patients and the toxicity may be dose related, discontinuation of lithium is frequently undertaken in an acute course of ECT. Some observations in bipolar mania have concluded that lithium may be used with ECT, particularly at low dose. History of cerebrovascular disease and head injury raises the risk of combining lithium and ECT. For continuation and maintenance ECT, doses are often withheld for 24 hours prior to treatment, allowing for washout, and markedly diminishing the chance of negative interaction.

Anticonvulsants can increase seizure threshold, decrease seizure expression, and may interfere with the efficacy of ECT, particularly in depressed patients. Interference with clinical outcome appears less marked in manic patients administered ECT with anticonvulsants, although there is increased frequency of missed seizures. When used for control of a seizure disorder, anticonvulsants are continued but held until after treatment sessions, unless poor seizure expression along with weak response occurs. In this circumstance, levels of drug may be re-evaluated in consultation with neurology. If anticonvulsants are used for psychiatric indications, they are generally tapered and discontinued, particularly in bipolar depression, to prevent a negative effect on clinical response.

Benzodiazepines are also anticonvulsants, but more often used for psychiatric indications. There are reports of diminished efficacy when benzodiazepines are used in conjunction with ECT, especially right unilateral electrode placement. As a result, this class of medications is tapered to the least necessary dose, discontinued, or substituted with other agents, for example, melatonin, low-dose trazodone, antihistamines, and agents with short half-lives, for example, zalephon. If use of benzodiazepines is considered necessary for management of severe behavioral syndromes, agents with shorter half-lives are preferable and should be withheld several hours prior to treatment. Use of flumazenil to reverse benzodiazepines has been reported, but requires further study and benzodiazepines may need to be administered during recovery to abort possible withdrawal. Little is known about the interaction of other sedative/hypnotics with ECT.

Anesthetists have been averse to allowing the use of monoamine oxidase inhibitors (MAOIs) concurrently with elective anesthesia, due to a potential for interference with management of cardiovascular abnormalities that may arise at treatment. ECT seldom results in a situation where the use of indirect-acting vasopressors, which would not be metabolized because of interference by the recent use of MAOIs, is necessary. Hence, the literature includes many reports of the safe performance of ECT in the presence of MAOIs. Current practice allows for consultation between the psychiatric and anesthetic practitioners as to the best recommendation for any particular individual or practice setting.

An augmenting effect for neuroleptics when combined with ECT in schizophrenia can be accepted with some confidence. As discussed previously, the combination treatment is more effective than ECT alone and may be more effective than medications alone. A few older studies even suggest that the long-term outcome of schizophrenia may be enhanced by combination treatment. Whether the acute or long-term effects carry over to other psychotic conditions is not clear. Most of the published data involve the use of typical neuroleptics, It appears that low-potency typical antipsychotics may be proconvulsant; haloperidol and fluphenazine appear to have little impact on parameters of seizure quality. The use of ECT combined with atypical neuroleptics appears to be safe. Clozapine and olanzapine have been observed to have proconvulsant properties and quetiapine, anticonvulsant properties. Atypical antipsychotics are also reported to have U-shaped functions with respect to convulsant properties. Because of these circumstances, dosing of neuroleptics should generally be in the moderate range. The only antipsychotic that cannot be combined safely with ECT is reserpine.

Earlier work with tricyclics (tricyclic antidepressants [TCAs]) and MAOIs provided some evidence to recommend the use of antidepressants to augment ECT. A recent RCT found that nortriptyline increased the response rate to ECT by about 15%; nortriptyline was also associated with diminished adverse cognitive effects. The combination of ECT and antidepressants is common practice in many parts of the world. Increasingly, in the United States, psychotropics, including antidepressants, are continued during a course of ECT because of expanding limitations placed byz insurers on utilization of mental health resources. It appears that TCAs are safe in noncardiac populations, and SSRIs in most populations, although they can increase seizure duration. After a series of cases where asystole occurred at doses of venlafaxine greater than 225 mg even with the concurrent use of atropine, it may be advisable to limit the dosage of venlafaxine if it is combined with ECT. The well-known proconvulsant effect of bupropion does not appear to pose safety issues with ECT, which has notable anticonvulsant properties. It is unknown whether newer medications, including selective MAOIs, now used more frequently for depression have augmenting effects. There is a limited data on stimulants, but there is risk for hypertension, dysrhythmias., and effects on seizure threshold. Cholinesterase inhibitors used in cognitive disorders appear safe, but do not enhance ECT including cognitive adverse effects. Finally, there has been limited interest in pharmacologic approaches to mitigating the cognitive side effects of ECT. Preliminary data using physostigmine, thyrotropin-releasing hormone, and naloxone have been published, but whether clinically significant effects could be obtained remains in doubt.

PHYSIOLOGY, ADVERSE EFFECTS, AND CONTRAINDICATIONS TO ECT

ECT is generally low risk and one of the safest procedures performed under general anesthesia. Estimated risk of serious complications, occurring in about 1/1,000 patients, is similar to that of general anesthesia for minor medical procedures. Risk of death, likewise in the range of that observed for such procedures, was estimated in a recent pooled analysis of 15 studies (766,180 treatments) at about 2.1/100,000 patients in modern populations undergoing ECT. Some believe that these rates of serious complications and death are lower than those related to the use of antidepressant medications, for example, TCAs. Causes of death in the first 30 days post ECT: falls and pneumonia most common, but not clearly related to ECT. Long-term mortality rates for hospitalized patients receiving ECT are lower than for patients receiving other forms of treatment.

Cardiovascular System

The ECT procedure routinely results in parasympathetic outflow during and immediately after the electrical stimulus. Unopposed by anticholinergic medications, sinus bradycardia and even brief, clinically insignificant, asystole can occur as a result. In patients over 50 years old, supraventricular ectopic beats are common, but clinically insignificant. In vulnerable patients, vagally related arrhythmias can occur such as atrial, junctional, and nodal rhythms as well as atrial flutter, and atrial fibrillation. Following parasympathetic stimulation, sympathetic output increases, mainly during the electrical stimulation and postictally when the adrenal gland also releases catecholamines. As a consequence, heart rate, blood pressure, and, perhaps, most importantly, rate pressure product increase. These increases peak immediately postictally and drop off within minutes to pre-ECT values, although in those over 50 years, normalization takes up to 1 hour for blood pressure and longer for heart rate. There can be a short period of decreased heart rate at about 5 minutes post-ECT. Related abnormalities of cardiac rhythm can include bigeminy and trigeminy, which are generally benign. Repolarization abnormalities such as T-wave changes and ST segment depression can appear infrequently. Ventricular tachycardia, usually nonsustained, and fibrillation can occur rarely. About 55% of those with pre-existing cardiovascular abnormalities will manifest some abnormality in the course of ECT. About 10% of one sample manifested transient increase in troponins of uncertain clinical significance.

With judicious pretreatment evaluation of both the risks and benefits of ECT, cardiac consultation, and the stabilization of any underlying disease, many of the more serious cardiac complications can be avoided. Uncontrolled hypertension, recent myocardial infarction (MI) (4 to 6 weeks), unstable angina, decompensated CHF, severe aortic stenosis, uncontrolled atrial fibrillation, and abdominal aortic aneurysm (>5 cm) pose enough risk to require close evaluation for suitability. About 90% of these patients will be able to complete a course of ECT safely. For example, ECT has been administered to patients with histories of pulmonary hypertension, subacute MI, abdominal aortic aneurysm, and Takatsubo syndrome. CHF patients with ejection fractions over 30% have been able to tolerate ECT. In patients with MI, a period of time must be allowed for healing, but the risk relates not only to the time elapsed but also to the severity of resulting cardiac compromise. As with arrhythmias and CHF, stress testing can be informative in deciding whether a patient can tolerate ECT. The presence of a pacemaker or device to abort arrhythmias is not a contraindication to ECT. ECT has been administered without complication to stable patients with transplanted hearts.

Respiratory System

Along with cardiac complications, adverse events related to pulmonary function are a leading cause of morbidity and mortality associated with ECT. The use of muscle relaxants leads to the cessation of breathing and oxygen is delivered by positive pressure through mask substitutes. Where patients have underlying pulmonary disease, exacerbation of asthma or COPD is possible, as well as excess secretions and aspiration. Pulmonary function should be optimized pre-ECT, and inhalers used before each session. Excess secretion can be addressed with anticholinergic medication. Aspiration can be mitigated by strict adherence to NPO pre-ECT, but obesity, pregnancy, neurologic compromise, DM, hiatal hernia, tube feeding, and medications causing hypersalivation, for example, Clozaril, increase risk. Immobilized and catatonic patients are at increased risk for peripheral venous thrombosis and pulmonary embolism. Risk can be mitigated by evaluation for anticoagulation, compression stockings, and prescribed physical activity. Rare cases of negative pressure pulmonary edema have been attributed to inspiration against an obstructed airway or mechanical irritation precipitating laryngospasm; it can also be neurogenically induced, for example, as a complication of status epilepticus. With proper preparation pre-ECT and careful anesthetic technique, these events are uncommon. Obstructive sleep apnea poses risk or may even be discovered during ECT anesthesia; it can generally be managed acutely with preoxygenation, and the use of nasal pharyngeal airway or laryngeal mask. Another rarely observed complication is prolonged apnea. This can result from decreased respiratory drive related to COPD, central apnea, medullar infarct, and slow metabolism of succinylcholine, due to cholinesterase or pseudocholinesterase deficiency. Supportive therapy suffices to manage this complication, and subsequent sessions of ECT can be given with very low–dose succinylcholine or a nondepolarizing agent. Cholinesterase inhibitors used for the treatment of Alzheimer disease have not been associated with prolonged paralysis or apnea.

Central Nervous System

Central Nervous System Seizure induction results in a hypermetabolic state characterized by increased blood flow with significant elevation in oxygen and glucose consumption. Increased blood–brain barrier permeability has been hypothesized due to capillary hypertension. Postictally, metabolic suppression develops. These physiologic changes have not been demonstrated to produce structural brain changes or damage in well-designed and controlled animal and human studies or by brain imaging or analyses of cerebrospinal fluid. There is insufficient energy, even at maximal output of a modern brief pulse device, to cause brain tissue injury by temperature elevation.

ECT can be complicated by prolonged seizure duration, defined as greater than 3 minutes by motor or EEG measurement, in 1% to 2% of treatment sessions. The risk is greater in adolescents and young adults. There is a risk of structural brain injury along with cardiovascular and pulmonary complications if the seizure persists beyond 30 minutes, even when oxygenation is adequate. Termination at 2 to 3 minutes is undertaken using parenteral anticonvulsant medications, for example, parenteral benzodiazepines, propofol, or the short-acting barbiturate used for anesthesia. If this fails, a standard protocol for status epilepticus treatment should be instituted and the patient transferred to a setting for emergency treatment if not already in one. Patients who experience prolonged seizures need to be reassessed for underlying etiology. Prolonged seizures are more common in the presence of proconvulsant medications such as theophylline or lithium or when more than one seizure is induced in a single session. They are also associated with medical conditions that decrease seizure threshold, such as electrolyte abnormalities and epilepsy. Nonconvulsive status should be suspected if there is lack of recovery from anesthesia or abnormalities in mental status persist. This state may be detectable by ECT device EEG monitoring, but can be present when the typical 2-lead EEG does not exhibit abnormalities. Risks for NCSE include history of epilepsy, CNS pathology especially frontal lobe disorders, abrupt taper of antiepileptic medications, and medications that decrease seizure threshold. Treatment with IV benzodiazepines is generally the first approach. Tardive seizures are rare. The rate of onset of new seizure disorder after ECT does not exceed baseline rates in the general population. Because of its anticonvulsant properties, ECT can be given safely to patients with epilepsy.

Before the development of brain imaging, deaths and neurologic deterioration were reported when ECT was given to patients with occult brain tumors and brain metastases. Evaluation, including radiologic procedures, of patients with neurologic findings or abnormal mental status now most often leads to the identification and treatment of such diseases prior to any administration of ECT. It is possible for ECT to be given safely to patients with small, slow-growing tumors without associated increased intracranial pressure, such as meningiomas. ECT has also been given to patients with healed skull and brain trauma, including craniotomy, as long as any skull defect is avoided. Patients may also experience transient CNS symptoms of almost any variety, for example, various cortical sensory abnormalities.

Depression not uncommonly complicates CNS disease such as stroke and dementia. If patients with stroke are neurologically stable 30 days after a cerebrovascular event, ECT may be given. Attention should be paid to the treatment and stabilization of the underlying cause of the stroke as well as to the current neurologic status. Patients with dementia receive ECT for complicating depression, but are at risk for greater adverse cognitive effects, such as delirium or prolonged confusion. There is interest in using the treatment for agitation complication dementia, but little supporting, controlled evidence is currently available. Treatment using techniques focused on mitigating cognitive effects, such as right unilateral electrode placement, specific tailoring of dosage, brief or ultra-brief pulse waveform, and twice weekly frequency, are often employed. Signs and symptoms of CNS lesions or increased intracranial pressure, such as papilledema, focal neurologic deficits, and abnormal brain scan require careful consideration prior to prescription and administration of ECT.

Dental

Due to direct stimulation of jaw muscles during delivery of the electrical stimulus, patients bite down, sometimes strongly, and unstable teeth may be broken or dislodged completely. Also vulnerable are front teeth with crowns or other dental modifications such as laminates. The approach to this complication is routine prophylactic screening and may necessitate dental consultation and procedures prior to ECT. If teeth are injured during treatment, care must be taken to remove any broken fragments before respiration resumes, when they may obstruct the patient’s airway.

Musculoskeletal

With the consistent use of muscle relaxants, the most serious of these adverse effects is only of historical interest. Before the development of curare and later succinylcholine, fracture of the long bones or spine occurred in up to 10% of patients as a consequence of unmodified movements associated with seizure induction and expression. The modern patient, who receives enough muscle relaxant to modify movement rather than fully abolish it, has no significant musculoskeletal complications. Those with skeletal disease, for example, osteoporosis, are more fully paralyzed for treatment. Although this complication has been almost completely abolished, older adult patients remain at risk for falls during a course of ECT and appropriate fall precaution protocols should be used.

More common in the modern era and, ironically, often an adverse effect of depolarizing agents, is myalgia. These muscle pains are most often a consequence of the fasciculations produced during depolarization and are most prominent after the first treatment, but seldom persist after a few more sessions. Myalgia can be managed symptomatically with analgesics.

Those patients with temporomandibular joint problems may experience an exacerbation of pain, resulting from the unmodified contraction of jaw muscles during stimulus delivery. Spasm can also be induced. Prophylactic approaches may be advisable, such as the use of dental appliances already in the patient’s possession or the administration of prophylactic analgesics such as nonsteroidal anti-inflammatory medications. Symptomatic post-ECT approaches may also suffice.

Neurocognitive

Cognitive side effects are a limitation to the use of ECT, although in recent years the syndrome of postoperative cognitive dysfunction has been detected in patients undergoing medical procedures requiring either regional or general anesthesia with up to 10% to 20% incidence, particularly those over 60 years. With ECT, these effects have been best described for depressed populations. Most of the reports of cognitive function in schizophrenic and even autistic populations show stable cognitive function after a course of ECT. The phenomena are made more difficult to discriminate because depression itself is accompanied by impairments in attention, concentration, and learning. Post-ECT, with remission of depression, attention, and concentration are improved. Several factors influence the likelihood and extent to which impairments develop, but response to treatment is not a variable in the development of the cognitive adverse effects of ECT. Furthermore, functions such as reasoning, creativity, and the ability to form memories, are not affected in any enduring fashion. Nondeclarative memory, that is, procedural memory and priming, does not appear to be affected either. It is also important to note that objective measurement and subjective report of cognitive side effects do not correlate for many measures of subjective memory with the exception of global assessment.

The first factor in the development of adverse cognitive side effects is time point in treatment, which influences not only severity, but the type, of effect observed. Disorientation, diminished processing speed, decreased anterograde and retrograde memory, and errors in visual–spatial function and word finding are greatest immediately after a treatment session. These effects diminish fairly quickly once the treatment course ends. There is preliminary evidence that reactivating and reconsolidating a semantic memory may make it particularly vulnerable to impairment. Except for retrograde memory impairment, other cognitive effects generally return to pre-ECT baseline or even improve over baseline with right unilateral ECT. Diminished processing speed can persist when sine wave ECT has been administered. Retrograde memory improves more gradually, but spotty deficits may persist, with recent memories for public information more vulnerable than older memories for personal experiences. Retrograde memory deficits may persist several months after treatment ends. In a community setting, 12.4% of patients manifested marked and persistent retrograde amnesia, defined as deterioration in autobiographical memory of at least two standard deviations from pre-ECT baseline at 6 months post-ECT. The only significantly correlated technical factor was the number of bilateral ECT; female sex was the only demographic or clinical factor to achieve significance.

The likelihood of developing adverse cognitive effects is influenced by technical factors in the treatment: bilateral electrode placement; inefficient stimulus waveforms, most particularly, sine waveform, but including brief pulse; markedly suprathreshold dosing; greater frequency and number of treatments; and larger doses of anesthesia are more likely to result in deficits during the acute and subacute course of treatment. Bilateral electrode placement is associated with greater likelihood of persistent retrograde memory deficits long term. There is mixed data on the relative cognitive profiles of bifrontal versus bifrontotemporal electrode placement. In recent decades, sine waveform, which are no longer recommended, have been largely replaced by brief pulse and, most recently, ultrabrief pulse stimulation, and much has been learned about optimizing right unilateral electrode placement and restricting dosage while maintaining efficacy. The advantage of ultrabrief pulse stimulation over brief pulse stimulation in cognitive side-effect profile has become more apparent in the past decade of increasing use of ultrabrief pulse waveforms (Table 33.20a–3).

Patient characteristics and clinical factors also impact the frequency and severity of adverse cognitive effects. Those with baseline neurologic disease, MRI abnormalities, and baseline impairments in global cognitive functioning are more vulnerable to developing deficits, as well as older and female patients. The concurrent use of certain medications such as lithium or medications with anticholinergic effects also increases the risk of adverse cognitive effects. There have been no well-established pharmacologic approaches to attenuating adverse cognitive effects, although there is interest in using NMDA antagonists, such as ketamine anesthesia, antiglucocorticoid agents such as mifepristone, and thyroid hormone.

Table 33.20a–3.
Treatment Factors Influencing the Degree of Adverse Cognitive Effects From ECT

Treatment Factor	Technique Associated With Fewer Adverse Cognitive Effects
Electrode placement	Right unilateral
Stimulus waveform	Ultrabrief (and brief) pulse
Stimulus intensity	Threshold determination; dosage closer to threshold
Number of treatments	Fewest necessary to achieve remission or plateau of target symptoms
Frequency of treatment sessions	Less frequent, e.g., twice weekly for acute treatment course
Number of seizures per session	One
Concomitant psychotropic medications	Discontinue lithium, sedatives; moderate dose of neuroleptics
Anesthetic dosage	Adjust dosage to produce lighter anesthesia; use ketamine

Perhaps because subjective memory correlates best with mood, and the majority of patients respond to ECT in systematic research, most patients studied in these settings report improved cognitive function post-ECT. It has been difficult to distinguish these patients from controls in the subjective assessment of memory months after ECT in randomized controlled trials. In community settings, which are characterized by inclusion of a broader range of patients and ECT techniques, subjective complaints of memory impairment are more frequent and correlate to the number of bilateral ECT received. Nonetheless, generally favorable attitudes are expressed by patients who have received ECT, especially compared to attitudes of the general public, and the majority of patients would have treatment again if necessary.

Other Adverse Effects

Postictal agitation has an undefined etiology, but can be associated with various factors, including electrode placement, electrical dose over seizure threshold, seizure duration, anesthetic dose, concomitant use of medications, and anxiety or agitation pre-ECT. Although ranging in severity, the more severe forms of agitation require emergent management with decreased stimulation, medications such as short-acting benzodiazepines, and ECT anesthetics, and even restraints. Prophylaxis may include switching electrode placement to unilateral, attention to electrical dosing, increasing the dose of anesthetic agent pre- and post-ECT or switching to propofol, modifying the dose of succinylcholine to prevent awakening while paralyzed or to decrease lactate generation, and alteration of medication regimens to address agitation by the use of neuroleptics. Lithium and carbidopa are associated with increased frequency of postictal agitation and should be evaluated for discontinuation or reduced dose.

ECT may be associated with a number of less serious, although nonetheless, uncomfortable side effects as well. Headaches and nausea can occur postictally. The etiology of postictal headache is unknown, and ascertaining cause is complicated by the presence or withdrawal of medications and the fact that anxiety often accompanies target illnesses for which ECT is used, such as depression. The throbbing quality of the headache suggests a vascular component, and migraineurs certainly seem more vulnerable to developing this side effect. Symptomatic management with analgesics, including nonsteroidal anti-inflammatory drugs, is often sufficient, but use of these agents prophylactically, for example, IV ketorolac, may be required. Migraine sufferers may need to use migraine specific treatments.

Nausea may accompany headache or occur alone in a minority of patients. Again the etiology is complex, including the use of anesthetic agents. Antiemetics, including $5HT_3$ antagonists, such as ondansetron or dopamine antagonists such as compazine, can be employed symptomatically. Change of anesthetic to propofol may also be effective.

FUTURE DIRECTIONS

There is interest in continued refinements of ECT technique. Common themes in these approaches are as follows: focusing the treatment spatially to optimize dosing in brain areas associated with putative neural networks involved in depression and other psychopathologies that are indications for ECT and to diminish dosing in areas associated with adverse cognitive effects and improving the efficiency of a noninvasive electrical stimulus in direction and amplitude, even to a subconvulsive level. Methodologies such as magnetic induction of convulsive treatment and focal electrically assisted seizure therapy are examples of innovation designs under investigation. This research is parallel to investigations in magnetic stimulation, for example, rTMS, and to the renaissance of invasive electrical techniques, for example, vagal nerve stimulation and deep brain stimulation.

33.20b Brain Stimulation Methods

STEFAN B. ROWNY, M.D., M.F.A., AND LAWRENCE AMSEL, M.D., M.P.H.

Brain stimulation in psychiatric practice and research uses electric current, or changing magnetic field, to induce currents within the brain to alter neuronal firing. There is a growing list of tools capable of eliciting such neuromodulation, each with a different spectrum of action and therapeutic utility in psychiatric disorders. These tools either apply electrical or magnetic fields transcranially or involve the surgical implantation of electrodes to deliver electrical currents to a cranial nerve or to the brain tissue directly. The transcranial techniques include cranial electrical stimulation (CES), electroconvulsive therapy (ECT), transcranial direct current stimulation (tDCS, also called direct current (DC) polarization), transcranial magnetic stimulation (TMS), and magnetic seizure therapy (MST). The surgical techniques include implanted cortical stimulator (ICS), deep brain stimulation (DBS), and vagus nerve stimulation (VNS). These methods are briefly described in Table 33.20b–1. ECT and DBS will be discussed in separate chapters.

Table 33.20b–1.
Brain Stimulation Methods: Definitions

CES	**Cranial Electrical Stimulation** Weak alternating electrical current is applied via saline-soaked felt-covered electrodes, usually to the earlobes or bifrontal scalp location.
cTMS	**Controllable pulse shape Transcranial Magnetic Stimulation (TMS)** A transcranial magnetic stimulator with a modified circuit that can induce nearly rectangular pulses, in contrast to conventional TMS that induces cosine waveforms.
DBS	**Deep Brain Stimulation** A wire electrode with multiple stimulating sites that is surgically implanted into the brain and chronically administers electrical stimulation.
ECT	**Electroconvulsive Therapy** Electricity is applied transcranially via electrodes placed on the scalp to induce a seizure under anesthesia.
MST	**Magnetic Seizure Therapy** High intensities of TMS are applied to induce focal seizures under anesthesia, as a less invasive form of ECT.
PAS	**Paired Associative Stimulation** TMS is paired with peripheral nerve stimulation, resulting in Hebbian plasticity, altering functioning of the corticospinal tract.
tDCS	**Transcranial Direct Current Stimulation, also called DC Polarization** Weak direct electrical current is applied to the scalp via sponge electrodes to polarize underlying brain tissue.
TBS	**Theta Burst Stimulation** High-frequency bursts (e.g., 3 pulses at 50 Hz) of TMS are applied at a regular frequency (e.g., 5

	bursts per second). TBS can be given continuously (cTBS) or intermittently (iTBS).
TES	**Transcranial Electrical Stimulation** Alternating electrical currents applied to the scalp.
TMS	**Transcranial Magnetic Stimulation** Rapidly alternating magnetic fields are applied to the scalp to induce small, focused electrical currents in superficial cortex. Remote sites may be activated trans-synaptically.
TNS	**Trigeminal Nerve Stimulation** Mild electrical current stimulate branches of the largest cranial nerve—the trigeminal nerve—either externally or subcutaneously aimed at modulating activity in brain areas such as the anterior cingulate cortex, nucleus solitarius, locus coeruleus, vagus nerve, and the cerebral cortex.
VNS	**Vagus Nerve Stimulation** An implanted pacemaker administers electrical pulses to the vagus nerve in the neck, activating the vagal afferents.

The historical roots of modern brain stimulation in psychiatry can be traced to the introduction of ECT in 1938 by Ugo Cerletti and Lucio Bini. Since then, electrical methods for neuromodulation have been in continuous use in psychiatry. ECT, which uses alternating electrical current applied to the scalp to induce a seizure, has been substantially improved over the intervening decades, both in refinements to the electrical stimulus characteristics and the placement of electrodes, as well as in advancements to the accompanying anesthesia, particularly with the use of muscle relaxants (e.g., succinylcholine, atracurium). In 1949, another alternating current brain stimulation method, CES, was developed in the former Soviet Union. It was originally called “Electrosleep” and, as the name suggests, was initially used to treat insomnia. This method uses much lower levels of alternating current than ECT and is thus subconvulsive. In 1985, nearly 50 years after the first use of ECT, Anthony and colleagues published the first use of pulsed magnetic fields to stimulate the brain with a procedure called TMS. TMS was initially used in neurology for studies of nerve conduction but quickly caught the attention of psychiatrists eager to explore other, less invasive alternatives to ECT. This nonconvulsive, well-tolerated stimulation method through TMS has been approved by the FDA for the treatment of depression. It also continues to be under active study, with some promising results in the treatment of various other psychiatric disorders like bipolar disorder, post-traumatic stress disorder (PTSD), obsessive-compulsive disorder (OCD), schizophrenia (as described by Lefauchear and colleagues in 2014), addiction disorders, particularly nicotine dependence, and even depersonalization disorder. MST is also a convulsive treatment in which the seizure is induced by the application of rapidly alternating powerful magnetic fields. It was first tested in an animal in 1998 and in a human in 2000. Since then, MST has been under investigation in nonhuman primates and in humans as a more focal means of inducing seizures in an attempt to retain the unparalleled efficacy of ECT but with fewer side effects.

Two more invasive brain stimulation methods, DBS and VNS, were introduced about a decade following the first trials of TMS. Both DBS and VNS were first approved by the U.S. Food and Drug Administration (FDA) in 1997 with indications for the treatment of neurologic conditions: VNS was originally approved as adjunctive therapy in reducing the frequency of epileptic seizures in adults and children aged 12 years and over; while DBS was initially approved for the treatment of essential tremor and Parkinson tremor. Currently, indications for DBS include treatment of all symptoms of Parkinson disease, including tremor, slowness, stiffness, involuntary movements induced by medications, as well as symptoms of OCD that are not adequately controlled with medications or other therapies. At present, indications for VNS include adult treatment-resistant depression and epilepsy.

Frequently, initial developments in brain stimulation have come from neurology. For example, TMS, DBS, and VNS originated as tools to treat neurologic conditions, but psychiatrists quickly saw the potential of those tools in the treatment of psychiatric conditions. It was not clear, however, whether those technologies and doses designed to treat neurologic indications could be directly coopted for the purposes of treating mental illness. Today, brain stimulation techniques in psychiatry are undergoing considerable research to answer those questions and many others that have emerged, and stimulation technologies are gaining momentum in psychiatry as they continue to evolve.

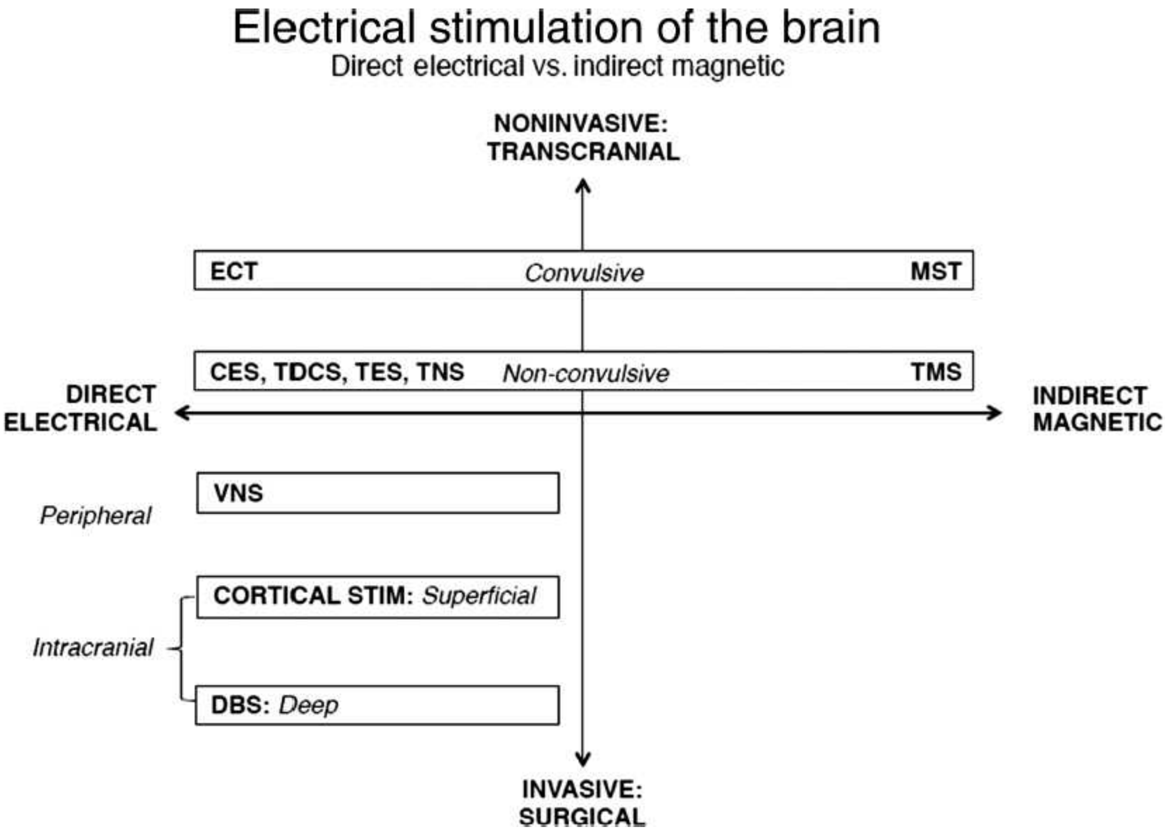
THERAPEUTIC NEUROMODULATION: TREATING PSYCHIATRIC DISORDERS THROUGH BRAIN STIMULATION

Mechanism of Action

Electrical Stimulation—Common Pathway. The brain stimulation tools considered in this chapter generate either electrical or magnetic pulses. However, both of these share a common final pathway—they affect the neurons electrically. That electrical effect may either be through the direct application of electricity and the resultant electrical field that reaches neurons or through the indirect induction of electricity via magnetic stimulation. The direct forms of electrical stimulation are exemplified in either *transcranial* delivery, as with ECT, CES, TNS, and tDCS, or surgical *intracerebral* delivery, as in the case of DBS, or direct cortical stimulation (epidural or subdural). The indirect forms of electrical stimulation include TMS and MST, which induce electric fields in the brain through the application of alternating magnetic fields (Fig. 33.20b–1). Of note, both the epidural and intracerebral modalities are more localized, referred to as focal, than the transcranial application of electricity because electrodes are placed directly in the neuronal tissue, bypassing the impedance of the scalp and skull. Magnetic stimulation methods also bypass the impedance of the scalp and skull. Hence they are also more focal when compared to the transcranial direct application of electricity. Magnetic stimulation is considered an indirect method of electrical brain stimulation in that changing the magnetic field from these devices induce electric currents in the brain according to the principle first described by Faraday in a law that bears his name and later incorporated into Maxwell’s equations, which unify all of electromagnetism. The magnetic modalities achieve their enhanced spatial resolution (focality) noninvasively, in contrast to the intracerebral and epidural methods. Therefore these modalities are at the center of intensive research as they offer a promise of an unparalleled degree of spatial specificity without the need for surgery.

All but one of the brain stimulation modalities described here act by stimulating neurons; the one exception is tDCS, which does not stimulate but rather it polarizes. In this sense, the “S” of tDCS is a misnomer. It is more accurate to conceptualize tDCS as exerting a polarizing effect aimed at altering the likelihood of neuronal firing.

The action of the subconvulsive modalities of stimulation relies on the effects of the repeated stimulation of the targeted neural circuitry. In contrast, in the case of the convulsive modalities (ECT and MST), the therapeutic action is dependent upon the seizure induced by the stimulation, and the subsequent effects of repeated seizures on brain processes. This is not to say that the form of stimulation that triggers the seizure has no impact on outcome itself (see later discussions of nonconvulsive electric stimulation). Indeed, it is well replicated that electrode placement and electrical stimulus parameters have a profound impact on the efficacy and side effects of ECT. Whether the same will be true for MST is under active investigation. Importantly, MST has the capability of inducing seizure in a more localized manner and thus targeting specific brain regions and their neuronal networks thought to be implicated in depression, while avoiding those responsible for untoward side effects.



Electrical stimulation of the brain
Direct electrical vs. indirect magnetic
NONINVASIVE: TRANSCRANIAL
ECT
Convulsive
MST
CES, TDCS, TES, TNS
Non-convulsive
TMS
DIRECT ELECTRICAL
INDIRECT MAGNETIC
Peripheral
VNS
Intracranial
CORTICAL STIM: Superficial
DBS: Deep
INVASIVE: SURGICAL

FIGURE 33.20b–1. Classification of tools that act to stimulate the brain electrically using direct (electrical) or indirect (magnetic) means.

Comparison of Brain Stimulation With Psychopharmacology. Psychopharmacology and brain stimulation differ in several clinically relevant respects. Pharmacologic agents rely on molecular action at synapses or at intracellular targets. They bind to either presynaptic or postsynaptic receptors or to intracellular targets in order to affect their function. In contrast, brain stimulation induces action potentials via electrical depolarization of axons or cell bodies independent of receptor activity. Thus, not only does brain stimulation have the potential to work when medications have failed, but it may also act synergistically with medications, as their respective sites and mechanisms of action are different. Because the chief mechanism of action in all modalities of brain stimulation is direct electrical modulation of the brain's neuronal activity, this approach avoids the systemic side effects seen with medications which are orally introduced exogenous compounds distributed throughout the body to sites that have little to do with the intended target. These compounds may be secondarily metabolized to other biologically active metabolites. In contrast, brain stimulation involves no exogenous compounds that circulate systemically in the bloodstream, does not undergo metabolism and clearance, is not protein bound, and has no known interactions with the metabolism or clearance of pharmacologic agents.

Brain stimulation is applied in a phasic fashion, which simply means that in contrast to medications that can remain biologically available in a patient's body for hours to weeks, or even months in the case of injectable depots, electricity can be turned on or off, with a flip of a switch. Most of the contemporary brain stimulation modalities that administer alternating electric current—either directly or via electromagnetic conduction (e.g., ECT, MST, DBS, VNS)—deliver pulses, or collections of pulses otherwise referred to as trains of pulses, with each pulse typically lasting 1 ms or less and trains of pulses lasting up to 30 seconds. The phasic nature of brain stimulation provides immediate washout that is not possible for pharmacologic agents, which must be first metabolized and then cleared. While the transient on–off nature of brain stimulation has proved advantageous in research probing functional roles of certain brain areas, it poses a challenge to the induction of lasting effects that will persist beyond the period of the therapeutic stimulation (see Table 33.20b–2).

Table 33.20b–2.
Brain Stimulation Versus Psychopharmacologic Therapy

	Brain Stimulation	Psychopharmacology
Therapeutic Agent	Electrical or electromagnetic	Neurochemical
Temporal characteristics	Phasic	Tonic
Delivery	Verifiable on electronic or clinical record	Dependent on patient compliance
Site of action	Axonal depolarization	Molecular target
Distribution	Focally applied to the brain	Systemic, throughout the body
Duration of availability	Milliseconds to seconds	Typical half-life of hours to weeks
Dosing parameters	Intensity, frequency, intertrain interval, number of pulses, site of stimulation	Milligrams, blood level
Metabolism	None	Hepatic
Clearance	None	Renal
Interactions with metabolism of other agents	None known	Possible

Table 33.20b–3.
Acute and Prolonged Mechanisms of Action

Acute effects
- Phasic activation of neural circuits
- Observable motor responses (e.g., twitch)
- Temporary disruption (e.g., speech arrest) or facilitation of ongoing processing (e.g., speeds reaction time)

Prolonged effects
- Neuroplasticity
  - Changes in synaptic efficacy akin to LTP or depression
  - Alteration in neurotropic factors
  - Modulation of cortical excitability
  - Modulation of functional connectivity

Acute Versus Prolonged Effects. Brain stimulation can have immediate or lasting effects (see Table 33.20b–3). A single electrical pulse delivered at sufficient intensity can induce depolarization, trigger an action potential, release neurotransmitters at the synapse, and result in trans-synaptic propagation with subsequent activation of a functional circuit. For example, brain stimulation applied to the hand area of the primary motor cortex may activate the corticospinal tract and induce a motor-evoked potential in the contralateral hand. Such stimulation can result acutely in the induction of either a positive effect, as in the case of a muscle twitch or visualization of phosphenes, or a disruptive effect as in the case of visual masking. Although inducing a muscle twitch is and immediate, short-lasting effect, it allows one to examine the latency of this effect from the time of the TMS single-pulse stimulation. One can thus determine the nerve conduction delay, a finding which may have value in the study of central motor pathways in clinical cases such multiple sclerosis and spinal injury.

Repetitive pulses delivered at fixed frequencies can exert even more powerful effects. Epstein and colleagues described in 1999 how repetitive TMS (rTMS) applied to the language-dominant hemisphere-induced arrest of speech. Following termination of the stimulation, speech returned to normal. More recently, in a study with cats, researchers used interleaved functional neuroimaging with rTMS to examine network-wide effects, and demonstrated behavioral impairments to visual attention with rTMS over the left intraparietal sulcus. Interestingly, they also found downstream adaptive compensatory activity in areas of the visual attention network that were not stimulated.

Some of the more invasive brain stimulation modalities, such as DBS or VNS, are programmed to operate chronically, thus extending the acute action for as long as the stimulation is turned on. In the case of DBS, the pulses are typically given continuously at a high frequency, whereas in the case of VNS the pulses are given in trains lasting up to 30 seconds and typically repeated every 5 minutes. The less invasive modalities, such as rTMS, tDCS, CES, and even ECT, may require the induction of some form of neuroplasticity for their effect to become lasting.

Neuroplasticity. Persistent activation of a brain circuit can induce prolonged changes in the subsequent activities of that circuit. For example, repeated stimulation of the prefrontal pathway is implicated in spatial memory learning and consolidation at a high electrical frequency; the stimulation induces a lasting increase in the efficacy of that circuit; conversely, repeated stimulation with low frequencies depresses it. These phenomena are termed long-term potentiation (LTP) and long-term depression (LTD), respectively, and are collectively known as neuroplasticity. Neuroplasticity is thought to occur through dynamic alterations in the synaptic architecture and efficacy. Establishing evidence of longer-lasting neuronal effects (i.e., LTP or LTD) from brain stimulation is crucial for establishing both the clinical utility and for understanding the mechanism of action. Recent research in animal models offers evidence of the lasting effects of high-frequency rTMS, and there is evidence emerging in humans that rTMS can produce changes in synaptic efficacy that outlast stimulation. Initially described by Wang and colleagues, low-frequency rTMS (1 Hz or less) is believed to induce a sustained inhibitory effect on the excitability of the motor cortex, whereas high-frequency rTMS (5 Hz or greater) produces facilitatory after-effects in excitability of the motor cortex. Esser and colleagues coupled TMS with topographical EEG measurements of TMS-evoked potentials. This work provided the first evidence that the changes in excitability may come about as a result of an enhancement of a cortical (voltage) potential. While such in vivo evidence is consistent with the hypothesis that TMS causes LTP (Esser et al., 2006) without ex vivo experiments on excised human tissue, it is difficult to say with complete certainty whether these observations are true measurements of synaptic plasticity.

Effect of Illness and Early and Late Brain Development on Brain's Response to Stimulation

Because brain stimulation exerts its acute effects by depolarization of neurons and over the longer term possibly through induction of lasting changes in synaptic efficacy, factors that influence pretreatment neural transmission and plasticity may influence the brain's response to therapeutic stimulation. For example, investigators have found that infants and children have higher thresholds for activation of functional circuits in response to single pulses of TMS, presumably because the myelination in their brains has not yet been completed. Diseases of the central nervous system can also impact the response to stimulation. Fitzgerald and colleagues (Fitzgerald et al., 2004) reported that patients with schizophrenia exhibited reduced plasticity in brain response to TMS when compared to healthy controls. Specifically, the patients failed to show inhibitory effects of low-frequency rTMS over motor cortex, possibly reflecting abnormalities in glutamatergic functioning in schizophrenia.

Cortical atrophy due to normal aging or disease-related can reduce the total dosage of magnetic stimulation delivered because the strength of the magnetic field drops rapidly as a function of distance from the stimulating coil. Aging can also alter the brain's response to stimulation in a manner independent of the distance issue. Some investigators have demonstrated an age-related differential response to rTMS over the motor cortex in older adults compared to younger subjects (45 years delineation of matched subjects), suggesting normal age-related changes in synaptic plasticity and the capacity for LTP and LTD that may reduce the efficacy of rTMS. These findings are in line with the generally accepted view that the efficacy of antidepressant pharmacotherapy is also highly age dependent.

Relationship Between Spatial Resolution and Invasiveness in Brain Stimulation

Each of the brain stimulation techniques can be separately classified with respect to the degree to which it can achieve precise focal targeting, that is, focality, and with respect to the degree of invasiveness, as seen in Figure 33.20b–2. A high level of focality is important when brain stimulation is a tool being used to map regional brain functions and is also advantageous in clinical practice provided that a specific target is known, or if stimulation of spatially adjacent regions might be counter therapeutic. On the other hand, if the target involves broad areas or is not precisely defined, then narrow focality may not offer benefits.

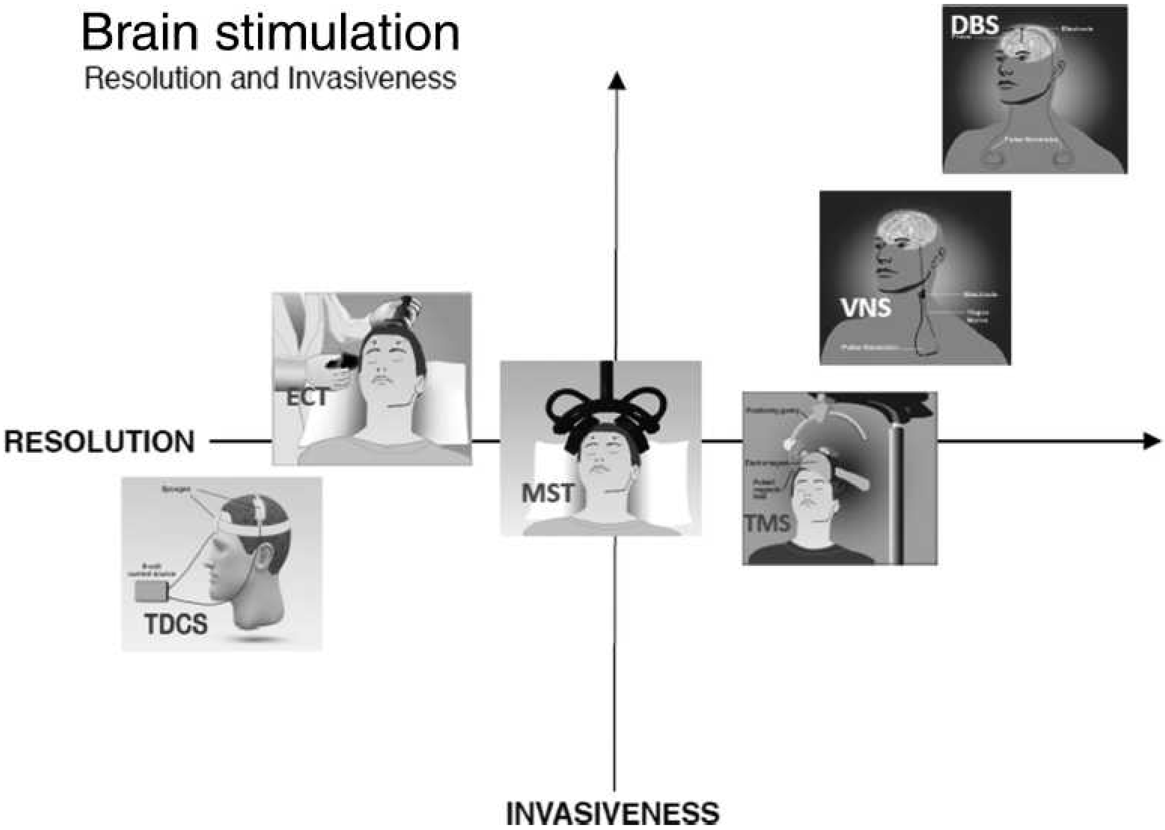


FIGURE 33.20b–2. Relationship between spatial resolution and invasiveness of the brain stimulation tools. DBS, deep brain stimulation; ECT, electroconvulsive therapy; MST, magnetic seizure therapy; tDCS, transcranial direct current stimulation; VNS, vagus nerve stimulation. (From National Institute of Mental Health, National Institutes of Health, Department of Health and Human Services.)

The least focal modalities are the noninvasive electrical stimulation methods such as tDCS, CES, and ECT. While ECT is more invasive by virtue of the need to use general anesthesia during the procedure and due to the induction of seizures, it is also nonfocal for the reasons it shares with the previous two methods—the electric current needs to traverse through the scalp and skull, which considerably impede the electric current, and which vary substantially from one individual to another.

The most focal or precisely targeted method is DBS, where a thin lead usually containing a number of wires connecting electrodes placed close to its tip, is implanted directly into the brain region being targeted. However, it is also the most invasive of all methods, requiring neurosurgical insertion of the stimulator lead, usually bilaterally, via a burr hole for each of the leads approximately the size of a quarter. Somewhat less invasive but also less focal is VNS, which stimulates the vagal afferents on their way to the brain. The magnetic modalities like TMS and MST are considered more focal because the magnetic field passes through the scalp and skull without impedance, in contrast to stimulation methods that directly administer electrical currents to the scalp. Magnetic flux has limited penetration (approximately between 2 and 4 cm), which is an important aspect of the stimulation's spatial resolution.

PSYCHIATRIC APPLICATIONS OF BRAIN STIMULATION

Dual Roles for Brain Stimulation: As a Probe of Brain Function in Health and Disease and as a Clinical Treatment of Psychiatric Disorders

Brain stimulation methods are used in psychiatric clinical and research practice along several parallel pathways. By virtue of their noninvasive nature, brain stimulation tools offer unique versatility as tools to examine normal brain function. By transiently perturbing brain activity, it creates temporary "virtual lesions" and allows for the monitoring of the subsequent effects on cognition and behavior. Such investigation is particularly valuable for probing brain areas implicated in the pathophysiology of psychiatric illness. Brain stimulation modalities are also used in the treatment of mental illness as novel therapeutic agents, as shown in Figure 33.20b–3.

Brain stimulation actively changes brain function and can induce measurable effects on brain activity that can be used to test the causal relationship between the brain and behavior. This is in contrast to neuroimaging or other methods of studying brain function that passively acquires information about brain function and can only provide correlates of behavior. To demonstrate the utility of brain stimulation in testing the causal relationship between the brain and behavior, Pascual-Leone and colleagues in 1991 created a virtual lesion in Broca area with rTMS, which consequently produced speech arrest in healthy participants. More recently, using brain stimulation to investigate pathology, investigators compared the impact of rTMS on participants with autism spectrum disorder (ASD) to healthy matched volunteers to demonstrate differential effects of stimulation. These variances suggest language-related neural network differences in those with ASD compared to neurotypical individuals.

In addition to examining brain–behavior relationships, the various stimulation modalities have the potential for delivering a therapeutic effect in the treatment of psychiatric disorders, primarily because brain stimulation modulates neuronal activity in a way that may be lasting, as reviewed in other parts of this chapter. The focal and temporal precision of some forms of brain stimulation poses a challenge in defining the disease-relevant anatomical and physiologic targets of psychiatric disorders. Improving the therapeutic use of neuromodulation in psychiatry will also require knowledge of the focal and distributed effects of the various stimulation paradigms.

Integrating Brain Stimulation With Neuroimaging and Neurophysiology

The combination of brain stimulation and functional neuroimaging is a powerful research paradigm for exploring and understanding neural circuitry. TMS, DBS, and ECT have been successfully coupled with positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and electroencephalography (EEG) to investigate the modulatory effects of brain stimulation in both healthy and pathologic populations. Commonly, physiologic measures are performed sequentially *offline* before and after brain stimulation to assess modulatory effects. However, for brain stimulation modalities such as TMS and tDCS, a simultaneous or *online approach* is now possible, whereby stimulation and imaging occur in an interleaved manner. Whereas functional neuroimaging alone can indicate correlations between brain and behavior, simultaneous neuroimaging and brain stimulation can indicate causal brain–behavior relations.

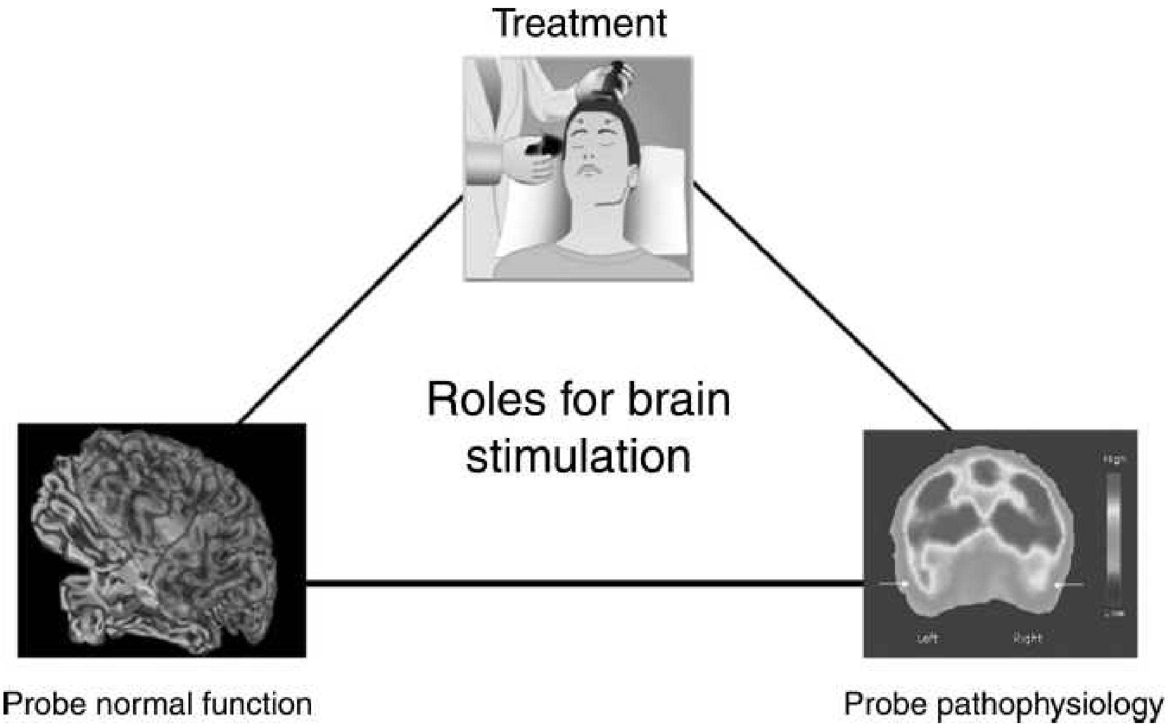

FIGURE 33.20b–3. Research and clinical applications of brain stimulation in psychiatry. (From National Institute of Mental Health, National Institutes of Health, Department of Health and Human services.)

With psychopathology increasingly conceptualized as dysfunction not of one isolated brain area but rather a dysfunction of a network of brain areas, the combination of brain stimulation and neuroimaging is useful for examining the dynamics of these brain networks and the functional roles of network components, which may be target sites for therapeutic stimulation. This is achieved by using brain stimulation to perturb or enhance one node of a network while monitoring activity in the entire brain. Results from such research elucidate the functional connectivity of brain networks. For example, researchers have found that stimulation with TMS of the angular gyrus resulted in modulated activity in remotely connected nodes of the visuospatial attention network (enhanced activity in the contralateral V1 and V2), in addition to the behavioral effects of TMS. In another example, investigators delivered low-frequency rTMS to the intraparietal sulcus, followed immediately by an attention fMRI task to demonstrate a decrement in activity in the targeted region and changes in activation of the corresponding contralateral region, as well as other regions in the visual attention network. In this experiment, rTMS appears to have produced changes in activity not only at the site of stimulation but also disrupted the interhemispheric balance of activity.

Interleaved brain stimulation and neuroimaging are also useful in guiding and localizing stimulation with much-improved accuracy rather than relying on gross structural anatomy as reference, which is susceptible to interindividual variability. In turn, accurately navigated TMS may reduce variability in clinical response.

These examples illustrate how combining brain stimulation with neuroimaging and physiologic measures can inform the exploration of mechanisms of action of various brain stimulation modalities. This can lead to effective screening of stimulation paradigms hypothesized to have therapeutic effects based on their ability to modulate the activity of specific circuitry implicated in the illness. However, combining neuroimaging methods with brain stimulation is not without limitations. For instance, the hemodynamic response as measured in fMRI is only an indirect measure of neural activity, and neuroimaging with interleaved brain stimulation is susceptible to artifacts.

BRAIN STIMULATION TOOLS

Transcranial Magnetic Stimulation

Definition. TMS is the application of a rapidly changing magnetic field to the superficial layers of the cerebral cortex, which locally induces small electric currents, technically referred to as “eddy-or Foucault-currents.” These are circular electric currents induced within a given conductor by a changing magnetic field in that conductor. Michael Faraday originally discovered this induction process through his experiments in 1831 which were later quantified in Maxwell’s equations that encompass all of electromagnetism. Thus, TMS may be referred to as electrical stimulation without an electrode, as it uses magnetic fields to indirectly induce electrical pulses in the targeted cerebral tissue. A TMS device delivers strong magnetic pulses via a coil that is held on the scalp. Since magnetic fields are unaffected by the electrical impedance of the scalp and skull, this method of stimulation enables the focal stimulation of smaller areas of the brain than is possible with other noninvasive devices which use either alternating (ECT, CES) or direct (tDCS) electrical current for primary stimulation. TMS is an example of noninvasive stimulation of focal regions of the brain delivered at levels well below the seizure threshold and, as such, can be used for research or therapeutics without the need for anesthesia. It is a relatively new treatment modality in psychiatric practice. The original device was approved by the FDA in 2008 for the treatment of depression in patients who have failed a trial of one, but not more than one, antidepressant medication like an SSRI. This initial indication has been since expanded to include another device and to treat adult patients with major depressive disorder (MDD) who have failed to benefit from any number of antidepressant medications.

TMS, when given one pulse at a time without regular rhythm and at low rates of delivery, is referred to as single-pulse TMS. When repeated at regular rhythmic intervals that usually range from 1 to 25 Hz, the method is described as rTMS, which can be further functionally divided into "low-frequency rTMS" when stimulation frequency is 1 Hz or less or "high-frequency rTMS" when higher frequencies are used, usually 5 to 20 Hz. Theta burst stimulation (TBS) refers to high-frequency bursts (e.g., 3 pulses at 50 Hz) applied at a regular frequency (e.g., 5 bursts per second). TBS can be given continuously (cTBS) or intermittently (iTBS). cTBS is reported to induce inhibitory effects, while iTBS is reported to exert excitatory effects.

History. In 1985, Barker, Jalinus, and Freeston from the University of Sheffield in the United Kingdom reported the first use of TMS to stimulate the human brain. Early stimulators were capable of producing only low frequencies, typically less than 0.3 Hz, but it was the single-pulse TMS that, in those early explorations, proved to be very useful in the study of motor conduction and mapping of basic brain processes. While these studies used large round coils that lacked the focality of today's technology, even this early work with low-frequency stimulation was promising enough in the experimental treatment of depression and schizophrenia to encourage development of TMS as a promising treatment modality in psychiatry.

With the subsequent development of devices capable of much higher repetitive rates up to 20 Hz—higher brain functions like language, mood, and memory became accessible to stimulation. In 1996, Pascual-Leone and colleagues (Pascual-Leone et al., 1996) reported that TMS stimulation for 5 days to the dorsolateral prefrontal cortex (DLPFC) might have antidepressant properties that are prolonged and maintained beyond the acute period of stimulation. Studies such as this motivated an intense interest in the potential therapeutic value of focally applied rTMS targeted to the neuronal circuitry underlying not only depression but also other psychiatric disorders like anxiety disorders, schizophrenia, and others.

Mechanisms of Action. By Faraday's Law, the induced electromotive force in a closed loop is directly proportional to the time rate of change of magnetic flux through the loop. As applied in TMS, a changing magnetic field induces an electrical current in the circuitry of the superficial cortex underlying the TMS coil. This electrical current is commonly referred to as an "eddy current" for its circulating motion in a plane perpendicular to the plane of the magnetic field (also known as Foucault currents, named after the French physicist who described the phenomenon). At sufficient intensity, electrical currents across the cerebral cortex affect cell electrochemical gradients and produce local neuronal depolarization, which may result in a propagated action potential. For example, when the TMS coil is positioned over the hand area of the cerebral cortex's motor strip, the changing magnetic field, generated by the repetitive pulses, induces local currents immediately below the site of stimulation, which cause the neurons in area M1 to fire. In turn, this action potential propagates through the polysynaptic corticospinal tract and results in a twitch in the contralateral hand muscle, which can be used to study the excitability of the corticospinal system. In summary, TMS uses changing magnetic fields to indirectly induce focal electrical currents in the brain, thereby triggering the firing of functional neuronal circuits that can lead to observable behavioral effects. This effect can be easily demonstrated by simply moving the TMS coil across the cortical representation of neighboring muscle groups (the homunculus) with a series of single TMS pulses and then observing different muscle groups twitching.

Single TMS pulses can exert other effects when moved to different cortical areas. When positioned over the primary visual cortex (V1), scotomas, or "blind spots," are often elicited. This effect was referred to as "visual masking" or creating a "virtual lesion," and it illustrates that TMS can transiently disrupt neural functions.

Activation of motor neurons resulting in a muscle twitch or disruption of visual perception with single-pulse TMS represents examples of the acute effects of TMS-induced neuronal depolarization, as shown in Table 33.20b–3. The effects of single TMS pulses are believed to be immediate and short-lived. The muscle twitch as induced by TMS to area M1 is nearly instantaneous, with the hand movement occurring approximately 20 ms after the TMS pulse is applied. Both the motor-evoked potential and visual masking operate on a similar timescale measured in milliseconds. While producing such a motor-evoked potential does not require the patient to engage in activity, a single magnetic pulse does not typically affect cognition. Rather, interference or improvement of performance in a cognitive task is observable when a train of magnetic pulses are delivered immediately preceding or during the time when the participant is engaged in a cognitive task.

Traditionally TMS coils were limited to direct stimulation of the cortical surface, activating neurons at 1.5 to 3.0 cm beneath the scalp rather than deeper subcortical limbic structures. However, recent development and research of coil designs for stimulation of deeper brain areas, such as the H-Coil, suggest TMS may stimulate subcortical structures up to 6 cm beneath the scalp. The cost of deeper stimulation, however, may be a spatially wider electrical field distribution in the brain (i.e., reduced focality).

TMS can exert longer-lasting effects when the pulses are repeated at regular intervals in a process of rTMS, or when TMS pulses are paired with other forms of stimulation, such as electrical stimulation of a peripheral nerve (as in Paired Associative Stimulation), or when TMS is coupled with audiovisual stimuli, as in the example of classical conditioning of the brain response to TMS. The mechanisms underlying these lasting effects of TMS have been described by various researchers and are thought to be related to neuroplasticity and alterations in synaptic efficacy.

Treatment of psychiatric disorders with rTMS has been informed by attempts to focally alter pathologic cortical excitability where irregular excitability has been linked to a specific illness. For example, reduced activity in the left DLPFC has been implicated in several studies as a physiologic correlate of affective disorders. To correct this, numerous studies have applied high-frequency rTMS, which purportedly increases excitability, to the left DLPFC in an attempt to normalize activity in this region. In a related approach, some investigators who believe that abnormal interhemispheric balance in activation between the right and left DLPFC is related to mood psychopathology, have applied low-frequency rTMS to the right DLPFC, in an attempt to normalize this balance with stimulation trains believed to be inhibitory.

The potential therapeutic role of rTMS to focally modulate cortical excitability has been validated in animal studies, which suggests that rTMS, like ECT and antidepressant medication, can exert effects on neurotransmitter release, receptor expression, and gene expression. However, animal models of the effects of rTMS do not perfectly replicate the effects of rTMS on the human brain due to size differences and consequently how they impact the strength and distribution of the induced electric fields.

Side Effects, Interactions With Medications, and Other Risks. Administration of TMS is a noninvasive, relatively benign procedure when applied by a knowledgeable professional to a subject who has been properly evaluated. However, it is not entirely without risk. The most serious known risk of TMS is an unintended seizure, but this risk varies depending on stimulation parameters and patient history. Namely, single-pulse stimulation is less likely to result in a seizure compared to rTMS and variations in dosage—the combination of frequency, power, train duration, and intertrain interval—may also change the risk of unintended seizure. In addition, subject factors such as the presence of a neurologic disorder (epilepsy or a focal brain lesion) or use of seizure-lowering medications may also result in greater likelihood of an unintended seizure. The FDA's safety guidelines for avoiding seizure with rTMS are summarized in Table 33.20b–4.

Table 33.20b–4.
Safety Guidelines for rTMS

	INTENSITY (% of Motor Threshold)													
Frequency (Hz)	80–100	100	110	120	130	140	150	160	170	180	190	200	210	220
1	>1,800	>1,880	>1,800	360	>50	>50	>50	>50	21	11	11	8	7	6
5	>10	>10	>10	>10	>10	7.6	5.2	3.6	2.6	2.4	1.6	1.4	1.6	1.2

Basic Studies. TMS has helped advance the basic understanding of normal brain function, as well as the pathophysiology of psychiatric illness. The combination of noninvasiveness, high temporal resolution, and particularly the ability to make use of frequency-dependent effects are significant advantages of TMS. Furthermore, the ability for TMS to be coupled with neuroimaging to explore the functional role of areas of activation seen with PET or fMRI imaging makes it a valuable tool for understanding brain function (see Fig. 33.20–4). For example, Luber and colleagues reported on the use of fMRI-guided stereotaxically applied rTMS to test the functional role of brain regions implicated in working memory. They found that rTMS applied to the precuneus facilitated working memory performance (Luber et al., 2007). Such an approach informs our understanding of the brain networks involved in normal brain function. Investigators have also delivered high-intensity TMS to participants during functional magnetic resonance image to demonstrate that stimulation of the left motor cortex was correlated with distributed cortical and subcortical activity in the bilateral premotor cortex, bilateral primary somatosensory cortex, bilateral second somatosensory cortex, left medial pontine nuclei, bilateral cerebellum, deep cerebellar nuclei, thalamic nuclei, and the basal ganglia (caudate and putamen). From such correlated changes in activity researchers are able to postulate brain areas that form distributed networks.

Clinical Studies. The use of rTMS in the treatment of MDD has been the most-studied therapeutic application of this technique. Evidence from a growing number of randomized controlled trials suggests a significant antidepressant effect with rTMS applied to the DLPFC. The largest study to date has been a multicenter trial conducted at four U.S. university hospital clinics reported by George and colleagues that included approximately 860 antidepressant medication-free patients with unipolar MDD who had not benefited from prior treatment. A total of 190 participants randomized to either active or sham treatment were included in the final analysis. Participants in the active treatment arm received daily left prefrontal rTMS for 3 weeks, with treatment standardized at 120% of the magnetic field intensity relative to the patient’s resting motor threshold, at 10 pulses per second (10 Hz) for 4 seconds, and an intertrain interval of 26 seconds. The authors reported that TMS was effective in treating major depression with minimal side effects. Not all studies have been positive, however, and the average effect size in depression is moderate—less than with ECT, but comparable to that seen with traditional pharmacotherapy.

Use of TMS in the treatment of schizophrenia has yielded some promising results in experimental studies that used either low-frequency rTMS to inhibit temporal–parietal areas of the cortex linked to hyperactivity during auditory or verbal hallucinations, or high-frequency rTMS to the prefrontal cortex aimed at modulating dopamine hypofrontality linked to negative symptoms. In the first double-blind randomized trial of deep TMS for the negative symptoms of schizophrenia, investigators found statistically significant reduction in negative symptoms after treatment, although there was no statistically significant difference between the active treatment and sham groups. Ongoing research has also demonstrated some positive results of TMS as a treatment modality in anxiety disorders and in OCD, panic, and Tourette syndrome.

Treatment Algorithms. In 2010, the APA included TMS within their Practice guidelines for the treatment of patients with MDD (3rd edition), recommending TMS as an initial treatment modality in the acute phase of depression. There are two FDA-approved TMS devices for use in adult patients with MDD: the NeuroStar TMS device manufactured by Neuronetics Inc. was approved in 2008 with the following FDA-approved indication: “for the treatment of MDD in adult patients who have failed to achieve satisfactory improvement from one prior antidepressant medication at or above the minimal effective dose and duration in the current episode”; and the Brainsway Deep TMS device that excites or inhibits neurons deeper inside the brain by using an H-Coil, was approved in 2013. The FDA-approved indication appears to be broader: “for the treatment of depressive episodes in adult patients suffering from MDD who failed to achieve satisfactory improvement from previous antidepressant medication treatment in the current episode.” The Neuronetics device delivers 10-Hz frequency pulses for trains of 4 seconds duration with an intertrain interval of 26 seconds and a typical session duration of 37.5 minutes (total of 5 daily sessions of 3,000 pulses for 6 weeks), while the Brainsway device delivers pulses with 18-Hz frequency for 2 seconds with an intertrain interval of 20 seconds and total trains duration of 20.2 minutes (5 daily sessions of 1,980 pulses for 4 weeks, followed by optional additional 12 weeks of biweekly maintenance treatments). A treatment course with either device is applied to the prefrontal cortex. At this time, rTMS treatments would most likely be considered as an alternative treatment modality to medications prior to more invasive methods like ECT.

Patient Selection. Patients who have failed a trial of one or more antidepressant medications are medication intolerant, and pregnant or postpartum patients avoiding the use of medications may be appropriate candidates for TMS. Notice that treatment of patients with a Neuronetics device who failed two or more medication trials in the current episode would be considered off-label based on its current FDA-approved indication. However, given the smaller effect size of TMS, for urgent or severely refractory cases, ECT would remain the ultimate “gold” standard treatment.

- Number of days/course
- Taper/maintenance/reintroduction

Dosing. The major characteristics of TMS dosing are shown in Table 33.20b–5. Each device’s technical parameters, such as stimulation intensity, pulse frequency, intertrain interval, and total number of pulses administered are the most basic adjustable elements of TMS dosing. In addition, coil shape and position relative to the target cortical area as well as the waveform shape and polarity, are also of important specific consideration (see Fig. 33.20b–5). In general terms, the delivered intensity of rTMS is related to the distance of the coil from the target area of the cortex. Thus, increasing the distance decreases the intensity of the stimulation able to reach the brain. Such decreased intensity has been found to be negatively correlated with the antidepressant response and with the degree of brain activation as evidenced by functional imaging. It is important to note that despite the many aspects that go into each device's dosing characteristics, considerable individual variability in the response to TMS has been reported.

Future Directions. TMS and other forms of magnetic stimulation hold a tremendous promise in psychiatric treatment due to their focality and noninvasiveness. However, much research is still needed to replicate preliminary findings with improved stimulators, optimize dosing, establish the patient characteristics that predict response, and examine the influence of concomitant medications on TMS effect. Research on the durability of clinical benefits of TMS is ongoing with some promising results. Using a large cohort of patients, investigators recently followed patients after their treatment for depression with TMS for 12 months post-treatment, and they found statistically and clinically meaningful durability of clinical benefits.

Other pursued directions are modification of pulse shapes to optimize stimulation as seen in controllable pulse shape TMS (cTMS), a device type that can generate rapid rate (<50-Hz) trains of mono/bi/polyphasic electrical pulses that are near rectangular in shape and vary in width, directionality, and amplitude. This work takes after the discovery in the 1990s, in the realm of ECT, of the benefits of square or rectangular waves of variable width compared with sinusoidal waveforms, which are generally now abandoned due to their inefficiency and creation of excessive cognitive side effects. In the first study examining cTMS use in human subjects, investigators found the cTMS device generated a broader range of pulse widths compared to conventional TMS devices, which these authors suggest could enable a more accurate study of the pulse width dependence of cortical excitability.

Another Innovation, which cleared FDA approval at the end of 2021, is poised to impact the delivery of TMS and is discussed below.

Stanford Accelerated Intelligent Neuromodulation Therapy

Definition. Intermittent theta-burst stimulation (iTBS), which obtained FDA approval in 2021, is a more efficient form of TMS, that can significantly shorten the duration of TMS treatment sessions from 37 minutes to 3 minutes and produces equivalent antidepressant responses. Building on this success a team at Stanford sought to further improve the efficacy and efficiency of iTMS through the following: (1) treating patients with multiple sessions per day at optimally spaced intervals, (2) applying a higher overall pulse dose of stimulation, and (3) using functional connectivity MRI (fcMRI) for individualized precision targeting of the left DLPFC. This approach is 6 to 10 times faster than conventional TMS.

History. The approved iTBS courses involve daily stimulation sessions (600 iTBS pulses) for 6 weeks and demonstrated remission in 32% of patients and response in 49%. The team at Stanford believed that this could be improved by accelerated, spaced delivery of stimulation sessions, higher overall pulse doses, and individualized targeting of the Left DLPFC. The Stanford Accelerated Intelligent Neuromodulation Therapy (SAINT) is a therapy that incorporates all three of these improvements and has undergone two trials. These will be described below.

Mechanism of Action. As there are several components to the SAINT improvements, it is difficult to disentangle their effects. However, some educated hypotheses are available. Instead of a single treatment per day, spread out over weeks, the SAINT protocol uses 10 treatments per day with a 50-minute spacing. This approach is believed to have an enhanced effect compared with the same number of single daily sessions. The 50-minute spacing in the SAINT protocol mirrors evidence that multiple-spaced sessions produce an accumulating nonlinear improvement in clinical symptoms, that is, they are potentially synergistic with each other when administered close together. The SAINT protocol also used higher doses, and it administers five times the overall pulse dose of the FDA-approved iTBS protocol, as well as a higher density of stimulation (90,000 pulses in 5 days, compared with the standard 18,000 iTBS pulses in 6 weeks). Previous studies found that individuals who do not respond to a TMS treatment course will respond with a higher overall pulse dose. And the higher pulse doses are generally associated with higher TMS efficacy. Finally, the authors conjecture that the use of the functional connectivity–guided targeting method used in the SAINT study may have contributed to the high remission rate because the left DLPFC is a large brain area that consists of several subregions, some of which are correlated and some anticorrelated with sgACC activity, and it is believed that stimulating the subregion of the left DLPFC that is anticorrelated with the sgACC is what reduces melancholic symptoms. So the authors believe this may be an important factor that accounted for their high response rate compared to other TMs studies. However, they fully recognize the need for further studies to confirm these mechanistic hypotheses.

Clinical Studies. There have been two studies on the SAINT protocol. In the first, the researchers demonstrated efficacy in a small cohort of participants with severe and treatment-refractory depression. The second study builds on that by testing SAINT in a larger and more generalizable cohort of participants with treatment-resistant depression. In the second study, they were able to demonstrate the feasibility, safety, and preliminary efficacy of this approach. There was one subject excluded. Thus, 19 of 21 who actually participated (90.5%) met remission criteria, and in the intent-to-treat analysis, 19 of 22 participants (86.4%) met remission criteria. This is an impressively high response rate for depression and higher than many existing treatments. If it stands up to further research, it will impact the field substantially.

Side Effects. Neuropsychological testing demonstrated no negative cognitive side effects, which will be a major factor in patients selecting this therapy if it becomes more available.

Future Directions. The impressive early results of the research into SAINT make it a serious contender for more broad use, especially for in-patients, who can conveniently tolerate the need to be available for long days of treatment and who would enjoy the much shorter total days of treatment involved. The cost of SAINT will no doubt come down as its effectiveness is recognized, making it more available and scalable across mental health systems.

Transcranial Direct Current Stimulation

Definition. Transcranial Direct Current Stimulation (tDCS) is a noninvasive and nonconvulsive form of brain stimulation in which a very weak (0.5 to 2 mA) direct electrical current is applied using at least two surface scalp electrodes in which optimal placement continues to be investigated. This DC form of electrical stimulation can be distinguished from most other devices that stimulate with alternating currents, such as

CES, TMS, ECT, MST, VNS, and DBS, and it does not directly result in neuronal firing by inducing suprathreshold neuronal membrane depolarization, Rather tDCS elicits polarity-dependent alterations in the resting membrane potentials. These facilitating or inhibiting effects can last for up to 1 hour after stimulation and are thought to induce neuronal plasticity. The device is very portable and usually operated by 9V DC batteries.

History. There is history of ancient Egyptian, Roman, and Middle Eastern use of live electric catfish and torpedo fish as crude therapeutic interventions that involved use of DC stimulation for headaches and epilepsy. It was not until the 1960s that tDCS was empirically investigated. In Great Britain, Lippold and Redfearn (1964) reported that positive (*anodal*) currents induced elevated mood and motor activity and reduced anhedonia, whereas negative (*cathodal*) currents induced withdrawal and apathy. While subsequent attempts to replicate these findings failed, since the 1980s there has been a growing body of evidence of positive effects from tDCS in cognitive and motor function. Of late, tDCS has experienced resurged interest due to its ease of application, small device size, low cost, and relative lack of risks and side effects as compared with treatments like ECT and TMS.

Side Effects. There are no known serious adverse effects of tDCS. It is well tolerated with a low prevalence of mild adverse effects reported in the literature, which include mild tingling sensations, mild itching sensations, skin irritation, mild burns, and headache.

Mechanism of Action. The mechanism of tDCS is assumed to be modification of the synaptic microenvironment, with weak DC either lowering or raising the membrane potential and, thus, the threshold of activation, in turn, this affects the firing and conductance of neurons. Specifically, anodal electrodes excite the neuron and shift the resting membrane potential toward depolarization, while cathodal electrodes inhibit the neuron by shifting its potential toward hyperpolarization. Moreover, these effects may be dependent on the subtype of cortical neuron being stimulated. Because tDCS works via polarization and does not affect action potential firing in cortical neurons, the term “transcranial DC polarization” is favored by some investigators and both terms appear interchangeably in the literature.

Clinical Studies. Much of the experimental research on tDCS has been conducted with healthy controls and demonstrates the effectiveness of this stimulation method in exciting and inhibiting brain activity. Preliminary research has also examined the effects of tDCS on neuropsychiatric disorders such as depression, schizophrenia, pain disorders, and epilepsy. While early research on the application of tDCS for depression produced mixed results, methodologic improvements have reignited interest in research of tDCS as a therapeutic technique.

Current clinical psychiatric research focuses on the potential effectiveness of tDCS in reducing depressive symptoms. A recent meta-analysis of seven randomized sham-controlled studies demonstrated significant antidepressant effects after left prefrontal anodal tDCS. There was a reduction of symptoms as measured by the Hamilton Rating Scale for Depression (HRSD), ranging from 14.6% to 80% in the active treatment group versus approximately 10% symptom reduction in the sham tDCS group. In terms of the durability of this clinical response, four of the seven studies reported that antidepressant effects were sustained for 1 month after the end of treatment in the active tDCS group. Further research is needed to confirm these findings.

Current Status in Treatment Algorithms. tDCS is not approved by FDA for psychiatric treatment and is thus considered an experimental research technology with much work needed to demonstrate its efficacy. Should sufficient evidence be attained and the device approved by the regulatory authorities, tDCS could represent an inexpensive and relatively safe alternative form of treatment to medications, or prior to the more invasive stimulation methods like ECT or VNS. Within research, the typically applied stimulation protocols are two cephalic electrodes positioned below the cranial foramina and fissures at 1 to 2 mA intensity, with stimulation up to 20 minutes per session.

Future Directions. Most of the current tDCS devices utilize large, saline solution–soaked electrodes. The recent development of high-definition tDCS (HD-tDCS) devices that use small arrays of high-definition electrodes are under investigation for their increased focality compared to standard bipolar montages of traditional tDCS devices. The results of an HD-tDCS 4 × 1 montage that consists of one center electrode over the target and four surrounding return electrodes are promising in terms of increased excitation of a target area.

In general, current knowledge of tDCS safety, efficacy, indications, and dose–response relationship, as well as predictors of response, is limited and further exploration is needed.

Cranial Electrical Stimulation

Definition. CES, like tDCS, uses a weak (1 to 4 mA) current. However, with CES, the current is alternating. It is traditionally applied via saline-soaked, felt-covered electrodes clipped onto the earlobes. Other placement strategies are also currently being investigated. For example, a study at Columbia University directed by Peter Bulow utilized a cathode placed over the scalp area immediately in the vicinity of the DLPFC and an anode placed over the right arm. The current doses used in CES are in a similar range to that of tDCS, with the major difference being that the current is alternating, creating either sinusoidal or modified square waves with very widely varying frequencies ranging from 0.5 to 15,000 Hz, depending on the type of the stimulator.

History. CES was originally developed in 1949 in the former Soviet Union and used as an aid in inducing sleep. It was thus called initially "Electrosleep." In addition to the treatment for insomnia, it was also utilized as an aid in anesthesia because of the observation that even when the current was reduced to the point of not causing excessive sleepiness, some patients seemed to benefit from the anesthetic effect of the stimulation. The device was brought to the United States, and early research in America dates back to the 1960s. It was grandfathered in by the FDA as a Neurologic Therapeutic Device for the treatment of "insomnia, anxiety, depression, and stress," and the name CES, for Cranial Electrotherapy Stimulator, was suggested. In the 1970s CES was used by many U.S. clinicians to treat substance abuse and substance abstinence syndrome, in the belief that patients with a history of abuse were more susceptible to cross-addiction to psychotropic medications and because they were thought to be more resistant to the effects of such medications when compared to nonaddicted persons.

Mechanism of Action. The exact mechanism of action has not been ascertained at this time, and there is no agreement among researchers on its mode of action. Previous hypotheses proposed that the stimulation with the alternating microcurrent affects the thalamic and hypothalamic brain tissue and facilitates the release of neurotransmitters. Claims have been made that through interaction with cell membranes, the stimulation produces changes in signal transduction cascades associated with classical second messenger pathways involving calcium channels and cyclic AMP. The most promising research on the mechanism of action comes from a neuroimaging study where researchers concurrently stimulated participants with CES. Investigators found that CES at both 0.5 and 100 Hz (two commonly used frequencies in clinical practice) deactivated frontal and parietal brain areas and significantly altered connectivity in the Default Mode Network. These researchers suggest CES, an oscillating current, may alter intrinsic brain oscillation patterns, which is in line with previous EEG research on CES. While such research is promising, possible therapeutic effects are still not well understood.

Side Effects. It is believed that the CES stimulation is not harmful, primarily due to its low-voltage power supply (9V battery) and lack of any reported adverse event by the FDA. However, local skin irritation, headache, nausea, as well as a general feeling of dizziness have been reported. Device manufacturers do not advise the use of the device during pregnancy, in those with low blood pressure, or people who have arrhythmias or pacemakers.

Clinical Studies. While there are over 40 years of research on CES, many studies lack a sham comparator or control measure, and many are open-label studies that lack rigor. A recent Cochrane Review suggests that at the current time, there are no high-quality studies comparing the use of CES with a sham treatment that warranted inclusion in the review, thus asserting that there is insufficient evidence to support the use of CES in treating acute depression.

In generalized anxiety disorder, a pilot study using a small sample of 12 patients receiving CES for 6 weeks at 0.5-Hz frequency and 300-μA intensity resulted in significant decreases in anxiety scores as measured by the Hamilton Rating Scale for Anxiety. While promising, much more research is needed.

Current Status in Treatment Algorithms, Patient Selection, and Dosing. Although the FDA approves a number of CES devices, the use of CES has not been studied sufficiently in the United States and it does not have a specific place in any algorithm of standard U.S. psychiatric practice. Routinely, CES used for depression is delivered daily for a minimum of 3 weeks followed by a reduced schedule as needed for up to a year. It is reported to be a generally well-tolerated, noninvasive treatment.

Future Directions. As with tDCS, basic issues of indications, patient selection, dose–response relationship, and efficacy are currently under active research and remain to be optimized.

Magnetic Seizure Therapy

Definition. MST is a novel form of a convulsive treatment, currently under development in several research institutions in the United States, Canada, England, Germany, and Australia. The treatment employs an alternating magnetic field that crosses the scalp and the calvarium, unaffected by their high electrical impedance, to induce a more-localized electric current in the targeted regions of the cerebral cortex than is possible with ECT. The aim is to produce a seizure whose focus and pattern of spread may be controlled. Numerous publications characterize MST as an attempt to combine the potential benefits of unimpeded focality provided by magnetic fields with the powerful antidepressant efficacy of ECT.

MST is a convulsive treatment, in many ways similar to ECT. It requires approximately the same preparation and infrastructure as ECT. However, MST is administered using a modified TMS device, one that can administer higher output than the conventional TMS devices and thus relies on magnetic stimulation to induce a seizure, unlike external electrode electric stimulation in ECT. The MST procedure is performed under general anesthesia with a muscle relaxant. MST is still at the stage of clinical trials and is not presently FDA-approved. Current studies concentrate on optimizing the efficacy by focusing on the putative depressive centers of the brain while avoiding those brain areas involved in memory formation and consolidation (medial temporal lobes), with the aim of lessening the acute cognitive side effects possible with ECT.

History. MST was first described as a convulsive treatment by Lisanby and colleagues in 2001. In Bern, Switzerland, a 20-year-old inpatient with a medication-resistant depressive episode was reported to have been successfully treated. The treatment resulted in a 50% reduction in depression scores, and it was well tolerated with no adverse effect on Mini-Mental State Exam Scores. Prior to this human treatment, magnetically induced seizures were first performed in rhesus monkeys in 1998 with a custom-modified TMS device, and later more extensive safety testing was completed with nonhuman primates.

The first trial of MST in the United States was performed at Columbia University in New York and reported fewer acute cognitive side effects with MST than with ECT in a within-subject, cross-over, blinded trial. The second center to perform MST in the United States was the University of Texas, Southwestern Medical Center. Internationally, small human trials are either ongoing or have been recently conducted at centers in Canada, Australia, Wales, Scotland, and Germany.

Mechanism of Action. Induction of a seizure is hypothesized to be the underlying event responsible for the mechanisms of action of MST. As in ECT, these are not fully understood. However, due to its focality, MST appears to represent a tool better suited than ECT to study the mechanisms of action of convulsive therapy through its potential to induce seizures that are initiated in different regions of the brain. This focality of MST allows systematic investigation of the coupling between the site of seizure initiation and outcome. Furthermore, the quality of seizures induced by MST is believed to be distinct from those induced by ECT. MST-induced seizures show less impact on parasympathetic outflow, less generalization to the hippocampus and deeper brain structures, and result in less serum prolactin surge.

Side Effects. Adverse effects from MST are largely connected to the risks associated with anesthesia and generalized seizure. In addition, MST magnetic coil produces a clicking noise that may potentially affect hearing. To mitigate that risk and prevent any cumulative damage, both the patient and members of the treating team should wear earplugs. Studies suggest MST results in less retrograde and anterograde amnesia than ECT. Specifically, investigators have demonstrated that there is significantly less acute memory disruption (i.e., anterograde amnesia on treatment days) with MST compared to right unilateral ECT. Though promising, this result needs replication in a larger trial.

Currently, MST seizures are less generalized and tend to produce less robust motor convulsions. For this reason, the dosage requirement of the muscle relaxant (usually succinylcholine) is lower than with conventional

ECT. Shortening the period of paralysis could reduce the risks of the procedure by reducing the period of respiratory suppression. It should be noted, however, that the attenuated robustness and generalization of the MST-induced seizures may be a function of cautious dosing with new technology. Further studies are needed, both on device development and the efficacy of dosing.

Clinical Studies. As mentioned, MST was used to treat a human patient for the first time in 2000 in Bern. A depressed patient received four convulsive sessions induced by a prototype MST device by Magstim (Magstim, Whitland, Wales, UK) using a frequency of 40 Hz at 100% of that prototype machine's power intensity. Soon after, a second human treatment case was reported by the same center, with both patients describing post-treatment relief of their depressive symptoms without experiencing any significant side effects. In 2003 after the first blinded, randomized, within-subject, crossover trial in 10 human patients, Lisanby and colleagues reported that there were fewer acute side effects of MST compared to ECT (Lisanby et al., 2003). A custom-modified Magstim device was used in this trial with the frequency increased to 50 Hz, a peak magnetic field of 1.2 T produced for 8 seconds, and a pulse width of 500 µs. One of the more important observations made in this trial was that although seizures were induced in all 10 patients, the seizure threshold was attained in several cases only at the very maximum of that device's power output. Since this experiment, there have been technologic improvements such that MST devices are now capable of continuous stimulation at 100 Hz for up to 10 seconds (Magstim device) and even up to 250 Hz for a limited stimulation time (MagVenture device). It has been shown that antidepressant effects of convulsive therapy require a suprathreshold stimulation requiring at least doubling and, in some cases, even six times more than the seizure-threshold power in order to achieve an optimal antidepressant result. Thus, the technologic improvements in MST more reliably ensure the induction of a seizure and may optimize clinical effects.

Convulsive treatment at 100 Hz was first used in 2004 in an ongoing study of rhesus monkeys and, starting in 2007, in human trials. Published results that compared MST to ECT in nonhuman primates continue to show a superior safety profile of MST, even with the newer high-dose MST device prototypes. Pilot trials investigating the efficacy and safety of the 100-Hz MST in human patients demonstrate promising results. Investigators at Australia’s Monash University and Alfred Psychiatry Research Centre reported on an open-label trial of 13 patients receiving three MST per week (a maximum of 18 treatments were provided) with a MagVenture device. These researchers found 5 out of the 12 patients who completed the study experienced a 50% reduction in depressive symptoms, and none of the 13 patients receiving the treatment demonstrated changes in cognitive functioning after treatment.

A randomized controlled trial comparing the efficacy of MST to ECT in 20 patients with treatment-resistant depression was reported by Kayser and colleagues at the University of Bonn. Six of 10 patients receiving MST in this study demonstrated a clinical response to treatment with a 50% reduction in depressive symptoms as measured by the Montgomery Åsberg Depression Scale and the HRSD, and there was no significant difference in efficacy or cognitive side effects when compared to the 10 patients who received ECT. Notably, the patients in this study receiving MST were significantly quicker to recover and reorient immediately after treatment and did not experience nausea, headache, or muscle pains that were evident in the ECT treatment group.

More recently, Lisanby and colleagues have been conducting multicenter, double-blind, randomized, controlled trials comparing the efficacy of right unilateral ECT and MST. They found that ECT and MST had the greatest effect on the factor consisting of core depressive mood symptoms: hopelessness (loading score = 0.77), depressed mood (0.61), work and activities (0.56), helplessness (0.53), worthlessness (0.44), psychic anxiety (0.40), and suicide (0.34). There was no difference between ECT and MST on the magnitude or speed of score reduction across these factors. They concluded that MST exerts similar antidepressant action across all symptom dimensions compared to ECT. In a related article, her team discussed the advantage of MST as potentially a personalized therapy based on the greater localization of seizure activity possible with MST compared to ECT.

Current Status and Treatment Algorithms. No clinical algorithms exist for MST, as it is still an investigational protocol, and treatments outside of research are not FDA-approved. There are two MST devices being used in research: the MagPro MST device with Twin Coil and Dual Coil manufactured by MagVenture that delivers a biphasic waveform and pulse width of 370 μs allowing a maximal stimulation with 2,000 pulses at 100 pulses per second at 100% energy output (effective 70% to 75% energy due to power roll off at those levels) or 1,000 pulses at approximately 67 Hz at 100% energy output; and a MagStim MST device manufactured by MagStim in the United Kingdom which has a maximum capacity of 1,000 pulses at 100 Hz with a single round coil, as in ECT, where parameters such as electrode placement, pulse width, and dose are essential to maximize clinical benefit while minimizing risks of cognitive side-effects, stimulation parameters, and coil placement are also important considerations in MST. Assuming the hypothesis that MST can approach the efficacy of ECT with fewer side effects is correct, this magnetically induced convulsive treatment will play an important role in the referral for convulsive therapy. Furthermore, should future technologic advances in the delivery of MSTAND combine with our improved understanding of the brain's circuitry implicated in depression, the result could be a treatment that is equally efficacious to ECT but with a more favorable side effect profile. In that case, MST could ultimately replace ECT altogether. However, much more research is needed both in the realm of clinical treatment efficacy and technologic device development.

Patient Selection. MST is investigated as a treatment alternative for those patients who have failed several adequate medication trials or whose symptom severity requires a fast treatment response, traditionally requiring ECT treatment. Since general anesthesia is an integral part of the procedure, MST will most likely continue to be reserved for treatment-resistant patients after several classes of medications have been already tried.

Future Directions. MST is a novel treatment in early phases of clinical testing. Clinical treatment variables, including dosing, optimal coil placement, patient selection, and mechanisms of action are the topics of ongoing and future studies.

Vagus Nerve Stimulation

Definition. VNS is a direct, intermittent electrical stimulation of the left cervical vagus nerve via an implanted pulse generator. The stimulating electrode is wrapped around the left vagus nerve in the neck and is connected to the battery/generator, usually implanted subcutaneously in the left chest wall. George and colleagues (George et al., 2000) described VNS in a paper in 2000 as an important new tool for brain research and therapy. As a result of electrode stimulation of the left vagus nerve, afferent signals are sent to the nucleus tractus solitarius and the connected limbic and cortical areas. Implantation surgery is completed under brief general anesthesia, usually performed as a day procedure, and involves two incisions—one in the chest for the battery/generator and another for the electrode in the left neck. Electrical parameters affecting the stimulation characteristics can be controlled by professional staff externally with a programming wand. Patients have the ability to switch off the pulse generator by holding a magnet over the skin directly above the area where it is implanted.

History. In 2005, VNS was approved by the FDA for the adjunctive treatment of chronic, treatment-resistant depression. It had been previously approved for the treatment of resistant epilepsy. More than 50,000 patients worldwide have received VNS.

Mechanisms of Action. The majority of the fibers contained in the left vagus are afferents. It is estimated that as many as 80% of these fibers are upgoing afferents, and thus chronic stimulation of these nerve fibers predominantly changes activity in the brainstem nuclei, such as the nucleus of the tractus solitarius and other neighboring nuclei (e.g., Raphe) that alter serotonergic activity in cortical and limbic structures. Additionally, persistent stimulation of the vagal afferents is anticonvulsant, an effect that appears to be dependent upon the norepinephrine-producing locus coeruleus.

Side Effects and Contraindications. Implantation of VNS is a minor procedure but carries a few risks. Besides the risk of perioperative infection, surgical implantation carries a small risk of vocal cord paralysis, bradycardia, or asystole. Stimulation also appears to be safe and generally well-tolerated. The adverse events that have been reported are coughing, hoarseness dyspnea, reversible bradyarrhythmias, obstructive sleep apnea, neck pain, and, most commonly, voice alteration. A long-term naturalistic study of VNS for major depression estimates less than 1% of patients have terminated VNS because of adverse events. Generally, there are no adverse cognitive side effects with VNS; on the contrary, research demonstrates performance on neurocognitive tests is significantly improved with VNS, likely due to the improvement in depression. However, modest cognitive impairment has been reported with higher stimulation parameters.

Outright contraindications to VNS include bilateral or left cervical vagotomy, use of short-wave diathermy and microwave diathermy, or therapeutic ultrasound diathermy. A special consideration may be that, in patients with implanted VNS devices, MRI imaging is not permitted, unless a special “send/receive” coil is utilized.

Clinical Studies. The first VNS study by Rush and colleagues (Rush et al., 2000) in 30 treatment-resistant depressed patients reported in 2000 showed response rates of 40% after 10 weeks of open-label, adjunctive VNS treatment and an initial remission rate of 17%. The response rate was sustained (46%) after an additional 9 months of VNS, while a further significant increase in remission rates, from 17% to 29%, was observed. Likewise, considerable improvements in patient functioning were also reported with long-term VNS treatment. Subsequently, in a report on an extended sample (*n* = 59), the short-term (3 months) and longer-term (24 months) effects of adjunctive VNS treatment revealed 10-week response rates of 31% (after 3 months), 44% (after 1 year), and 42% (after 2 years). Remission rates were 15%, 27%, and 22%, respectively, demonstrating continuous and stable improvement. By 2 years, 81% were still receiving VNS. However, a large 10-week randomized, sham-controlled, blinded, multicenter trial of VNS for treatment-resistant unipolar or bipolar depression later reported by Rush and colleagues (Rush et al., 2005) failed to show a significant difference in benefit on the primary outcomes between active and sham treatment after 10 weeks. On the other hand, an open-label long-term follow-up of the same cohort (*n* = 202) demonstrated increased response rates (27.2% response and 15.8% remission rates at 12 months), which was higher than response rates in a nonrandomized comparison group receiving treatment as usual (i.e., not VNS). The researchers did not attribute improvement in the VNS group to medication changes or a delayed placebo effect in such chronically ill patients.

Current Status in Treatment Algorithms. The FDA indication for VNS is for the adjunctive long-term treatment of chronic or recurrent depression in patients 18 years or older experiencing a major depressive episode in the setting of unipolar or bipolar disease, who have not had an adequate response to four or more adequate antidepressant treatments. Consultation with another clinician experienced with treatment-resistant depression and VNS is recommended.

VNS treatment success rates are lower than those with ECT. Response to VNS is relatively slow—typically only 15% of patients respond in the first 3 months, increasing to approximately 30%, after 12 months. VNS may be worth considering, therefore, when patients have failed to respond to less invasive treatments, ECT was ineffective, or post-ECT relapse cannot be prevented with less invasive means. VNS might be helpful with longer-term relapse prevention, but results of controlled trials would be needed to guide that practice.

Patient Selection. A stepwise approach to patient evaluation for VNS is outlined in Table 33.20b–6. VNS is approved as a long-term adjunctive treatment for chronic or recurrent depressive episodes in adults with a major depressive episode that has not had a satisfactory response to four or more adequate antidepressant trials.

Table 33.20b–6.
Evaluation for Vagus Nerve Stimulation

- Does this patient meet the U.S. FDA labeling criteria?
  - Unipolar or bipolar disorder in a major depressive episode
  - Long-term major depressive episode (≥2 years)
  - Recurrent depression
  - Inadequate response to four or more adequate treatments
- Have other causes of medication resistance been ruled out?
  - Medical, substance, personality disorders
  - Compliance with adequate doses and durations
- Can the patient tolerate a slow-acting therapy?
- Does the patient need acute response now?
  - Electroconvulsive therapy may be a better option for the acutely suicidal
- Get a second opinion

Table 33.20b–7.
Clinical Scenarios: Vagus Nerve Stimulation (VNS) or Electroconvulsive Therapy (ECT)

Acutely suicidal, in need of rapid response	ECT
Psychotic depression	ECT
Acutely depressed, medication resistant, never had convulsive therapy	ECT
Chronically depressed, able to tolerate slow onset of action	VNS
Had convulsive therapy before but always relapsed quickly despite adequate medication	VNS
Cannot be tapered off maintenance convulsive therapy, and it is not effective	VNS

Consideration of what constitutes an "adequate" trial requires careful assessment of not only whether adequate dosages were prescribed for an adequate period of time, but also whether the patient was reliably compliant. Optimally, such assessment should be substantiated by careful review of treatment records, pharmacy reports, and blood levels where appropriate. Failed trials should include different medication classes, including selective serotonin reuptake inhibitors (SSRIs) and selective serotonin/norepinephrine reuptake inhibitors (SNRIs), as well as tricyclic antidepressants, and monoamine oxidase inhibitors (MAOIs), and various augmentation strategies with or without ECT. A second opinion from a psychopharmacologist specializing in treatment-resistant depression and knowledgeable about VNS is advisable.

Clinical scenarios when ECT might be favored over VNS, and vice versa, are outlined in Table 33.20b–7. For example, VNS does not exert rapid antidepressant action and thus acutely suicidal patients and others in need of rapid response would be more appropriately treated with other strategies. VNS is indicated as a long-term treatment option only for those with chronic or recurrent courses of illnesses.

ECT and TMS have been safely used in patients with an implant when the VNS generator was turned off during the treatments, which is necessary for ECT because of the anticonvulsant effects of VNS. It remains to be studied whether VNS could be useful in relapse prevention post-ECT.

Dosing. There are varying stimulation parameters (i.e., current, pulse width, frequency, and duty cycle) that are determined by the treating physician, which can be programmed into the pulse generator via telemetry. Optimum dose–response parameters are still being researched, although a large multicenter clinical trial did not find significant differences in efficacy in treating depression between “low” (output current of 0.25 mA, pulse width of 130 ms), “medium” (0.5 to 1.0 mA, pulse width 250 ms), or “high” (1.25 to 1.5 mA, pulse width 250 ms) at acute phases (8 to 22 weeks) or chronic phases of treatment (25 to 50 weeks).

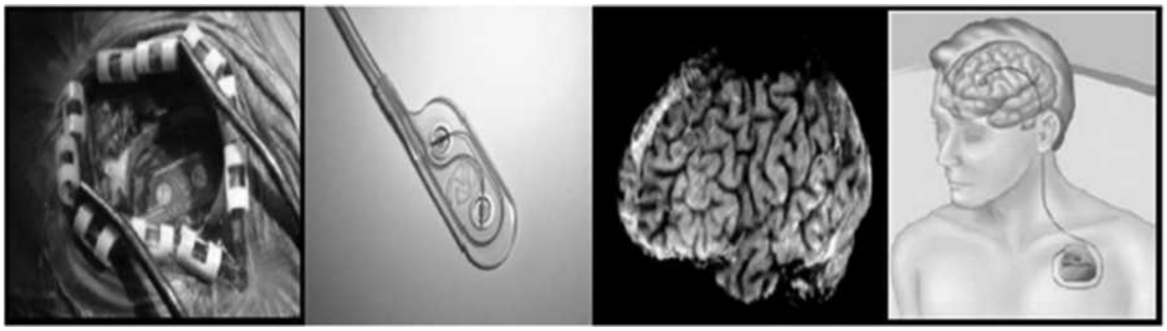

FIGURE 33.20b–6. Implanted cortical stimulator.

The epilepsy literature suggests that there is a threshold current for efficacy. Because the adverse effects of VNS are known to be dose-dependent, treatment parameters are often chosen to mitigate specific side effects. For example, lowering pulse width reduces neck pain, allowing patients to tolerate higher currents.

Future Directions. More research is required to establish the dose–response relationships for VNS. Future studies may explore optimal medication strategies to augment responses, test the potential role of VNS for long-term relapse prevention (e.g., after ECT), and study its mechanisms of action.

Implanted Cortical Stimulation

Definition. Cortical brain stimulation is a novel neurosurgical approach in which electrodes are implanted directly over the surface of the cortex to provide electrical brain stimulation in a targeted superficial region. This approach is being studied for the treatment of conditions such as stroke, tinnitus, and treatment-resistant depression. Because of its novelty, different investigators use different names to describe it, ranging from implanted cortical stimulation (ICS), through cortical stimulation system, to cortical brain stimulation, and direct cortical electrical stimulation (DCS). The stimulating electrode can be implanted relatively superficially in either epidural or subdural layers, but the specific topographic placement of the stimulator varies depending on the condition being treated (see Fig. 33.20b–6). For example, in psychiatric applications, investigators have reported on a trial involving an ICS in the superficial brain cortex area overlying the left DLPFC. The electrodes are powered by a pacemaker-like device that is implanted in the upper chest area.

History. ICS is an invasive but reversible form of brain modulation and, like DBS and other less invasive neuromodulation methods, stems in part from the psychosurgical treatments for severe mental disorders performed during the 1940s and 1950s. These early forms were highly experimental and often resulted in significant adverse side effects due to physical surgery in the brain tissue. Today, with the advancement in our understanding of the specific functional brain regions and their interconnections, as well as the relative ease of access to neuroanatomical and brain imaging studies, direct electrical stimulation is a safer way of either temporarily disrupting faulty function, enhancing deficient functions, or otherwise reversibly modulating abnormal brain activity.

Trigeminal Nerve Stimulation

Definition. Research of trigeminal nerve stimulation (TNS) in humans has been ongoing since 2001 and has been most commonly studied as a therapeutic intervention for drug-resistant epilepsy. However, TNS has been explored as an adjunct to pharmacotherapy in depression with positive results, and clinical trials of TNS for ADHD are currently underway. At this time, TNS is not approved for use outside of research, however.

Mechanisms of Action. Due to the anatomy of the three bilateral afferent cutaneous branches of the trigeminal nerve with connections to the nucleus tractus solitarius, locus coeruleus, and raphe nuclei, noninvasive stimulation of the V1 branch of the trigeminal nerve has therapeutic potential in the treatment of mood disorders and drug-resistant epilepsy.

Clinical Studies. Studies exploring the psychiatric applications of TNS are ongoing. Within epilepsy research, typical TNS treatment utilizes stimulation for at least 12 hours a day for 18 weeks. In a recent multicenter trial comparing high (experimental active treatment) and low frequency (active control) external TNS (eTNS) for the treatment of drug-resistant epilepsy, investigators reported that the response rates for high-frequency eTNS at 120 Hz with a pulse duration <250 μs and maximum off-time of 90 seconds were significantly greater (30.2% reduction in seizures) than low-frequency eTNS at 2 Hz with a duty cycle of 2 seconds on and 90 seconds off and 50-μs pulse duration (21.1% reduction in seizures).

Side Effects and Contraindications. TNS is generally well tolerated, with a low incidence of headache and skin irritation. Some patients report sensory experiences of tingling or vibration, and there have been reports of a significant increase in heart rate but no significant changes in blood pressure.

Future Directions. The simplicity of administering eTNS by applying a gel electrode on the forehead is a unique advantage over surgically implanted devices. Thus far, research demonstrates that bilateral TNS is more effective than unilateral stimulation and high-frequency TNS is more efficacious compared to low-frequency stimulations. As clinical benefits may increase with treatment course, longer treatment length may increase therapeutic effects.

Nonconvulsive Electrotherapy for Treatment-Resistant Unipolar and Bipolar Depression

Definition. While traditional ECT, in which a seizure is induced in the patient, is still the treatment with the most evidence for being an effective therapy for treatment-resistant major depression, many patients are reluctant to engage in this option due to their concerns about having seizures and the associated memory loss. Moreover, while repetitive transcranial magnetic stimulation (rTMS), VNS, and other approaches mentioned above are either FDA-approved, or have evidence for efficacy, the brain stimulation alternatives to ECT mentioned so far have lower efficacy for treatment-resistant patients than traditional ECT. Thus, in addition to the alternatives mentioned above, an emerging innovation to traditional ECT involves a treatment that is almost the same as ECT, but without the seizure induction, namely nonconvulsive electrotherapy (NET). NET involves similar electrode placement and use but the stimulation is kept below the doses that induce seizures.

Mechanisms of Action. While the mechanism of action is not known, clinical experience has shown that some patients who received subconvulsive electrical stimulation that failed to cause seizures never the less had a therapeutic effect. Moreover, both older human studies from the 1950s and more recent animal studies (showed that subconvulsive electrical stimulation elicited antidepressant-like effects. This led to the hypothesis that, at least for some individuals, the active ingredient in ECT was not the seizure but the stimulation.

Clinical Studies. While this is a new field in need of more research, a study of NET for the treatment-resistant unipolar and bipolar depressive disorder was conducted. This pilot, proof-of-concept study used an ECT device with a dose of electric stimulation below the dose that induces a seizure. The procedure still requires sedation with anesthesia but avoids the seizure, and the treatment was delivered using a bifrontal electrode placement. The study was performed on a small number of participants (n = 13), and the depression response and remission rates were 73% and 55%, respectively. Thus, this new adaptation of ECT could provide an additional treatment option for patients who struggle to respond to treatment.

Side Effects and Contraindications. Additionally, those results showed that NET could avoid the cognitive effects associated with ECT, as assessed by Mini-Mental State Exam and the Autobiographical Memory Inventory-Short Form. While formal cognitive testing was not performed, these preliminary results indicate that NET is likely to have fewer cognitive side effects.

Future Directions for Treatment of Resistant Depression. Currently, additional studies are being performed with NET in patients with treatment-resistant depression. In addition, it is being tested in other patient populations, including those with chronic pain, as described below.

Future Directions for Treatment of Pain. In a currently active study, Diana Martinez at Columbia University is investigating whether NET can be helpful in treating chronic pain. In this context, the technique is called transcranial electric stimulation therapy (TEST). In the procedure, electric stimulation is applied to the brain, and anesthesia is required, but, as in NET, the dose of stimulation is lower and does not cause a seizure. In the current trial, treatments are performed three times per week, just like traditional ECT, and measurements of pain, mood, and memory are collected before and after the sessions (ClinicalTrials.gov identifier [NCT number]: NCT05113563). It should be noted that there is prior literature on the use of traditional ECT for pain. However, traditional ECT involving seizures did not seem appropriate to many pain patients and their clinicians. Given the current crises in balancing the needs of chronic pain patients with risks of addiction and overdose, a nonseizure form of electrical stimulation, one without cognitive side effects, may add an important tool to the pain management armamentarium. The results of the study by Martinez are, therefore, of great interest to psychiatrists and pain management clinicians alike.

ACKNOWLEDGMENT

This chapter represents an update and revision of previous chapters in this series, most recently by Dr. Sarah Hollingsworth Lisanby from the last edition. We are indebted to Dr. Lisanby for their work and retain much of their prose in this current edition.

33.20c Neurosurgical Treatments

BENJAMIN D. GREENBERG, M.D., PH.D., AND NICOLE C.R. MCLAUGHLIN, PH.D.

Neurosurgical treatments for psychiatric illness continue to receive increasing attention. Clinically or in research, they are used in small, highly selected groups of patients with disabling illnesses proven intractable to conventional medication and behavioral therapies. Current techniques are vastly different from the crude freehand “psychosurgery,” especially prefrontal lobotomy, of the mid-20th century, which saw wide, often indiscriminate use. Stereotactic ablation is now MRI guided, vastly improving its accuracy. MRI-guided ablation using radiosurgery or the newer high-intensity focused ultrasound (HIFU) avoids craniotomy, while radiofrequency or newer laser ablation requires small, usually bilateral, craniotomies. Deep brain stimulation (DBS) also requires craniotomy for implantation. DBS can be stopped or modified if it causes adverse effects or is ineffective but requires indefinite follow-up by (relatively rare) specialized teams. In the United States, DBS for intractable OCD received FDA humanitarian approval in 2009 and is an approved treatment in the European Union. Other uses of DBS in psychiatric populations remain investigational. This chapter focuses on neurosurgery for otherwise intractable OCD, which also serves to illustrate general principles and procedures for potential uses of neurosurgery in other conditions. These include intractable major depression, eating disorders, addiction, Tourette syndrome, and other illnesses where research is ongoing; recent publications on those topics are cited in this chapter.

A large body of open-label clinical data supports the effectiveness and relative safety of modern neurosurgical interventions. An increasing body of controlled data has been reported, usually in relatively small studies, given the relative rarity of the “surgical” population. In tandem, an increasing body of systematically collected data on adverse events allows risk/benefit judgments to be better informed. Despite intriguing hypotheses and, recently, more physiologic data from intracranial recordings, the mechanisms of action of psychiatric neurosurgeries remain to be established, a situation that still parallels functional neurosurgery for movement disorders. While these treatments are sometimes criticized for this reason, neurosurgical interventions are similar to other therapies insofar as the most relevant issues are safety and efficacy, rather than correction of still poorly understood pathophysiologic processes.

Standards of care for psychiatric neurosurgery use strict criteria and a formalized practice. For Humanitarian Use Devices (i.e., DBS), there is oversight by a local Institutional Review Board (IRB). More generally, DBS or ablation is not approved unless a multidisciplinary committee reaches a consensus that a given candidate is appropriate, based on diagnostic evaluations and a detailed assessment of prior clinical course and treatments received. The informed consent process unfolds over time in the context of a thorough medical and psychiatric evaluation. At the time of this writing, surgical intervention is mainly reserved for patients with severe, incapacitating OCD who have exhausted conventional behavioral and medication therapies. The ethical context of psychiatric neurosurgery has increasingly seemed similar to that of any higher-risk procedure or research, for example, movement disorder neurosurgery.

Lesion procedures at first developed largely empirically and were then influenced by theories implicating cortical–subcortical systems in disordered behavior. DBS was, in turn, influenced by the experience with stereotactic ablation. For both kinds of procedures, neuroscience tools allow hypothesis generation with respect to potential neurocircuit and physiologic mechanisms of action, as does translational research in animal models. Such multidisciplinary work may inform other device-based techniques, both invasive and noninvasive. Brain stimulation using implantable devices that can respond selectively to patterns of brain activity putatively associated with symptoms (e.g., closed-loop or “responsive” DBS) has recently become a special focus of interest.

HISTORY

Trephination in prehistoric times was likely the earliest surgery for psychopathology. The first modern neurosurgical treatment in psychiatry was reported in 1891. These bilateral cortical excisions in patients with dementia and depression were described as yielding mixed results. In 1935, John Fulton and Charles Jacobsen reported that chimpanzees showed less fear in the “experimental neurosis” paradigm after frontal cortical ablation (lobectomy). The animals retained an ability to perform complex tasks, but fear expression was reduced. António Egaz Moniz, a Portuguese neurologist, attended Fulton’s 1935 lecture. Prompted by these findings, Moniz pioneered prefrontal leukotomy in collaboration with his neurosurgeon Almeida Lima. First, by using alcohol injections and subsequently mechanically using a leucotome (a kind of surgical knife), Moniz and Lima performed “psychosurgery” on 20 severely ill institutionalized patients; 14 were said to have exhibited worthwhile improvement. In an era of overflowing asylums and few effective treatments for debilitating illnesses, surgery was at first enthusiastically embraced. Moniz won a Nobel Prize in 1949 for this contribution.

From the mid-1930s until phenothiazines emerged in the 1950s, these techniques proliferated globally. Walter Freeman, a neuropsychiatrist, was perhaps the most zealous promoter of psychosurgery in the United States. Initially, he worked closely with neurosurgeon James Watts. They developed freehand procedures to achieve prefrontal lobotomy (i.e., severing white matter connections between the prefrontal cortex and the rest of the brain). Freeman and Watts reported on their first 200 cases in 1942. Although the benefits of the surgery were highlighted, others acknowledged a significant rate of complications, such as frontal lobe syndromes (including apathy and disinhibition), seizures, and even deaths. At its peak, lobotomy was being performed on approximately 5,000 patients per year in the United States alone. A review of 10,365 prefrontal lobotomies performed from 1942 to 1954 in Britain concluded that while 70% showed improvement, adverse effects included 6% mortality, seizures in 1%, and disinhibition in 1.5%. There were widespread reports of blunted personality and socially inappropriate behavior.

In the late 1940s and early 1950s, recognition of these risks prompted attempts to develop modified stereotactic surgical procedures that might yield better results. For example, Spiegel and Wycis, who began stereotactic neurosurgery in humans, reported in the 1940s that dorsomedial thalamotomies improved obsessive-compulsive symptoms. However, with the introduction of chlorpromazine (Thorazine) in 1954, medical management of psychiatric illness became newly possible. Thus, despite the advent of stereotactic neurosurgical techniques and a continued high prevalence of severe, treatment-refractory psychiatric illness, psychiatric neurosurgery was all but abandoned in favor of nonsurgical therapies. Later, as the limitations of neuroleptics and electroconvulsive treatment became known, there was a renewed interest in psychiatric neurosurgery at a few academic medical centers in the 1960s. Refinement of stereotactic methods and emerging theories regarding the role of the limbic system in emotion shaped a newer age of psychiatric neurosurgery. The pioneers of these contemporary procedures faced harsh opposition from political groups, as well as the general population, based largely on the results of crude and indiscriminately applied operations of an earlier era. Political and social pressure dissuaded all but a handful of neurosurgeons and psychiatrists from offering these treatments. Despite these societal influences, in the late 1970s, the authors of a U.S. National Commission report found, to their own surprise, that available evidence indicated that many patients benefited after lesion procedures. They advocated continued systematic research and a national data registry. Although the registry never materialized, gradually, over nearly five decades, research and education regarding modern neurosurgery led to its legitimacy as a treatment for severe, otherwise intractable psychiatric disorders, now with more refined practices and surgical procedures. Indications, expectations of benefit, and risks have become better defined.

PATIENT SELECTION

Indications and Contraindications

The best-established indication for psychiatric neurosurgery remains otherwise intractable OCD; there are also multiple reports of lesion procedures or DBS used in major depressive disorder (MDD). Factors considered during patient selection include the following:

1. *Primary diagnosis:* The patient must meet clinical criteria for the diagnostic indication, and this disorder should be a primary cause of the patient's debility and suffering.
2. *Severity and functional impact:* The patient must have a chronic, severe, and debilitating illness; the duration of the primary illness must exceed 1 year and typically exceeds 5 years. Severity is gauged on standardized instruments. Surgical candidates with OCD typically have Yale-Brown Obsessive-Compulsive Scale (YBOCS) scores of a minimum of 26 to 30 (of a possible 40). Debility should be indicated by standardized ratings of a low level of functioning and quality of life.
3. *Adequacy of previous treatment:* Patients must have already tried an exhaustive array of other available established treatments delivered by competent practitioners, who should typically be interviewed by the evaluating team after available medical records are reviewed. A thorough assessment of the adequacy of previous medication and psychotherapy trials is equally important and often requires interviews with treating psychotherapists as well as reviews of medical records. Medication trials must similarly be judged adequate; where appropriate, high-dose antidepressant trials (for OCD in particular) should have been attempted, with duration of each medication trial no less than 2 months.
4. *Psychiatric comorbidity:* Appropriate treatment must also have been rendered for any comorbid psychiatric disorder. Strong

relative contraindications include active psychoactive substance abuse or severe personality disorders, which may interfere with adherence to presurgical treatment trials or with the exhaustive evaluation and consent processes, or with the recommended postsurgical treatments and follow-up.

5. *Medical comorbidity and surgical fitness:* Structural brain lesions or central nervous system injuries of clinical significance are strong contraindications. Medical conditions that increase neurosurgical risks (e.g., cardiopulmonary disease) and age over 70 years represent a relative contraindication for lesion procedures, while DBS may be used, as for movement disorders, in somewhat older cases. A history of past seizures is a risk factor for perioperative seizures after lesion procedures and must factor into the overall risk–benefit assessment.
6. *Access to postoperative care:* The extensive evaluations and subsequent psychiatric neurosurgery mark the beginning of a new episode of care. It is crucial that patients have access to adequate postoperative treatment, including a psychiatrist (typically the referring physician) and a psychologist who will accept responsibility for managing the case after discharge. Arrangements for postoperative care (e.g., intensive behavior therapy) should be confirmed ahead of time. Importantly, after lesion procedures, care can generally be delivered in standard treatment settings without the need for highly specialized psychiatric neurosurgery teams. For DBS, access to specialized teams is essential over the long term. Once implanted, DBS patients require clinical monitoring and device adjustment, which can be intensive and time-consuming, especially but not only early in treatment. Device monitoring and replacements may need to occur on a relatively urgent basis. The continuing costs incurred can be substantial, and the adequacy of third-party reimbursement needs to be ensured in advance to the extent possible. After either lesion procedures or DBS, family or significant others may be needed to support and accompany patients to follow-up care, similar to the level of support that is usually necessary during the intensive evaluation process. Currently, DBS for intractable OCD is eligible for reimbursement

under an FDA HDE approval in the United States. However, actual reimbursement can vary. The procedure has full approval from the European Union. Other psychiatric uses of DBS remain investigational, an important consideration for reimbursement.

7. *Informed consent:* Under no circumstances should psychiatric neurosurgery be performed on an unwilling patient. The patient must be able and willing to render informed consent. Consent monitoring, including the use of structured consent feedback tools, may be considered to help ensure that the consent process is adequate. In rare instances, these procedures are performed with the assent of the patient and formal consent from a legal guardian. In this context, age less than 18 years represents at least a strong relative contraindication.

Multidisciplinary Case Review

Assessing candidacy differs somewhat from center to center and between nations, as governed by law. Across centers, particular importance is placed on case review by a group with the appropriate breadth of expertise. As noted above, decisions regarding candidacy must be made after a thorough review of the patient’s case, taking into account the written record, current clinical examination, and formal referral from the patient’s treating psychiatrist. In most U.S. expert centers, the decision is typically made by an interdisciplinary committee; in other countries, psychiatric neurosurgery may require additional formal review and approval from duly constituted national commissions or other procedures.

Available evidence strongly supports the idea that the group of patients for which neurosurgery might be appropriate represents a small proportion of the total of treatment-seeking individuals. For OCD, less than 1% of individuals in a large naturalistic study would meet current surgical criteria. Even when referred by clinicians, up to half of the patients in a different study were not accepted for surgery on the basis of either a questionable diagnosis or, most often, a conventional treatment that was judged inadequate. Another, more recent study of DBS for OCD found that of nearly 300 individuals clinician or self-referred for initial consideration for study entry, less than 10% eventually underwent DBS implantation.

PREOPERATIVE WORKUP

In addition to the above clinical evaluation and formalized review, the preoperative workup for psychiatric neurosurgery includes physical and neurologic examinations, standard presurgical blood and urine laboratory tests, as well as an ECG, plus specialized tests of brain structure and function. A comprehensive preoperative assessment should include brain MRI, psychometric testing using neuropsychological batteries that assess multiple domains, and in some cases, an EEG. This workup is broadly similar to that for DBS or lesion procedures for movement disorders.

POSTOPERATIVE CARE

Immediate postoperative care includes the usual medical and surgical management following any stereotactic neurosurgical procedure. Special attention is paid to signs or symptoms of potential surgical complications, including infection, hemorrhage, seizures, or altered mental status. For ablative procedures, a postoperative MRI should be obtained to document the placement and extent of lesions, timed to optimally visualize the evolution of the lesions; for DBS, imaging by CT assesses potential postimplantation hemorrhage. Over the longer term, intensive postoperative psychiatric treatment is recommended since the efficacy of the intervention may rely on the synergy between the neurosurgical intervention itself and enhanced response to pharmacologic or behavioral therapies. Although dosages of psychotropic medications might be reduced during the immediate perioperative period, the medication regimen should be readjusted as tolerated postoperatively. Moreover, in the case of OCD, intensive behavior therapy should be continued or resumed early, for example, as soon as the first postoperative month for DBS or by 3 months for lesion procedures (which include radiofrequency ablation, Gamma Knife radiosurgery, and the newer procedures of laser or high-intensity ultrasound ablation) where the clinical benefit is expected to evolve more slowly. Longitudinal assessment of patient adherence to medication and behavioral treatments is essential so that treating clinicians can intervene to optimize care if patients change their regimens on their own (as has happened in some cases postoperatively despite extensive preoperative advice that patients not change medications on their own).

For DBS, as noted above, electrode implantation is followed by immediate postoperative imaging (e.g., computerized tomography; CT scan) to assess for potential hemorrhage and evaluate general device placement. This is followed by a several-week recovery period to enable resolution of local edema and stabilization of other factors (e.g., pneumoencephaly) that might influence the response to stimulation. Postoperative imaging to more accurately visualize device locations (e.g., CT scan for fusion with preoperative MRI) may take place at that time. Then, a systematic electrode survey and adjustment of stimulation parameters are performed before initial settings are determined. This is usually done in the outpatient setting and is often a time-consuming process, lasting hours over 1 or more days. Ongoing protocols for DBS entail frequent follow-up, especially during the initial 6 months after implantation, to enable optimization of stimulation parameters, patient monitoring, and management, including coordination of pharmacologic and behavioral therapies.

DESIGN AND INTERPRETATION OF CLINICAL STUDIES

It is critical to appreciate the inherent challenges which continue to surround research in this domain. The patient populations in question are very challenging and can require intensive management over the months and years of a clinical trial. These populations can be very heterogeneous. High rates of comorbidity are the rule. The total numbers are small. As noted above, less than 1% of treatment-seeking OCD patients may be eligible for neurosurgery, and proportions of appropriate patients with major depression or other conditions are also likely to be small. As a result, the major U.S. psychiatric neurosurgical centers collectively treat a small number of cases yearly. Thus, statistical power is limited, as are estimates of efficacy and adverse effect rates. The major academic centers might have their own surgery of preference (sometimes more than one). Historically, centers have employed somewhat different measures for assessing treatment response, although methods are converging. Selection criteria have also varied somewhat across centers, especially for the earliest studies of a particular technique. Consequently, it is often difficult to contrast or combine data across different groups. Moreover, determining the cause of long-term postoperative improvement can be confounded by exposure to other new therapies as they emerge or even by the longitudinal course of illness. And improvement in function and quality of life have not been weighted as highly as changes in symptom severity, which are at least equally important.

LESION PROCEDURES

Although numerous approaches have been tried from the mid-20th century to the present, four lesion procedures have been the most used. All four entail bilateral lesions, performed using stereotactic methods. Two of them, anterior cingulotomy and anterior capsulotomy, are most used currently. For all ablative procedures, the outcome cannot be fairly assessed for a considerable postoperative period, which could extend up to 2 years. While effects of DBS may develop sooner, for example, within several months postoperatively, long-term follow-up remains essential to assess the durability of responses.

Anterior Cingulotomy

The first cingulotomies were performed for intractable pain, a practice that continues along with newer research into DBS of the anterior cingulum for pain. The clinical feature targeted is the affective component of pain rather than nociception. It was noted that pain patients with comorbid anxiety or depressive conditions had better responses. H. Thomas Ballantine Jr. and colleagues later found that anterior cingulotomy was relatively safe and studied its effectiveness for psychiatric indications. Since 1962, the group at Massachusetts General Hospital has performed well over 1,000 anterior cingulotomies. The surgery is conducted under local anesthesia, and two or three approximately 1-cc lesions are made, under MRI guidance, on each side by thermocoagulation through bilateral burr holes. The target is within the anterior cingulate cortex (Brodmann areas 24 and 32), at the margin of the white matter cingulum bundle. A subgroup of patients may undergo a second procedure months later, either a cingulotomy extension or the addition of subcaudate tractotomy. There has also been investigational use of DBS at the ventral capsule (VC)/ventral striatum (VS) target after cingulotomy.

In an early (1987) retrospective review of cingulotomy outcomes (*n* = 198, average follow-up 8+ years), from 56% to 79% of individuals with affective disorders, OCD, or anxiety disorders were judged improved on a global measure. A later prospective study of 64 consecutive patients undergoing cingulotomy for intractable OCD between 1989 and 2009, using the YBOCS for OCD severity and Beck Depression Inventory (BDI) for associated depressive symptoms, found full or partial responses (≥35% or 25% to 34% YBOCS severity improvement, respectively) in 35% or 7% a mean of close to 11 months postoperatively. Almost half had a repeat cingulotomy or subcaudate tractotomy by 5 years, when full or partial response rates improved to 47% and 22%, respectively. The severity of comorbid major depression decreased modestly from baseline. Psychiatric adverse events included suicide in 2 of the 64 patients (3%), one of whom had made a prior suicide attempt and the other had bipolar depression. Other adverse events, including those after repeat procedures, were mainly transient: memory impairment (8%), abulia (6%), urinary retention (3%), intraoperative or postoperative single seizures (6%), or infection requiring repeat surgery (1.5%). More recent reviews have demonstrated that about 38% to 47% of OCD patients who have received cingulotomy are full responders. As in the above study, nonresponders may also respond to a repeated procedure.

Anterior Capsulotomy

Anterior capsulotomy (or capsulotomy) was first performed by Tailarach and colleagues in France. Later, Lars Leksell and colleagues further developed the procedure in Sweden. Initially mainly done by radiofrequency thermocoagulation, Gamma Knife radiosurgery, with laser ablation (laser interstitial thermal therapy [LITT], see below) and HIFU are more recent developments. While earlier in capsulotomy, the entire dorsoventral extent of the anterior limb of the internal capsule was lesioned, modern procedures place lesions selectively within its ventral part impinging on the adjacent ventral striatum. This primarily interrupts fibers of passage between the ventral prefrontal cortex and subcortical nuclei, including dorsomedial and anterior thalamus. The term “ventral capsulotomy” is used to describe the newer procedure. Ventral capsulotomy may be performed as an outpatient procedure, with an overnight hospital stay usually the most that is required. Anterior capsulotomy is primarily used for OCD, though it has also seen use in major depression and other severe anxiety disorders.

In the 1970s, Leksell and colleagues reported on their first 116 cases of thermocapsulotomy (again, lesions included the entire dorsoventral capsule). They noted favorable responses in 50% for OCD and 48% for major depression. A subsequent larger review found adequate data in 213 of 362 cases. Of those 213, 64% were deemed to have benefitted substantially on global scales (i.e., were judged much or very much improved). Transient side effects included headache, incontinence, and confusion, the latter lasting up to 1 week. In a subset of 24 patients followed prospectively, there was one intracranial hemorrhage and one episode of seizure. Fatigue was seen in 29%, 17% had a poor memory, and 8% exhibited a lack of attention to appearance. Weight gain was a common enduring side effect with a mean increase in body mass of about 10%.

A 2008 study reported on 25 OCD patients who underwent thermocapsulotomy, Gamma Knife anterior capsulotomy, or both combined. It used disorder-specific rating scales and measures of adverse effects. Even though these patients had failed to respond to treatments unavailable to the earlier cohorts (thus, their illnesses might be expected to be more refractory than in the early experience), effectiveness was, in fact, comparable to that in the early work: 48% response and 36% remission using YBOCS OCD severity ratings. This series also demonstrated a notable adverse effect burden. Forty percent were judged to have a clinically significant frontal impairment (problems with executive functioning, apathy, or disinhibition). Most in this group had repeated thermocapsulotomy and/or high-dose Gamma Knife radiation resulting in larger lesions and which today would be avoided. In contrast to the early work, MRI was available and showed that smaller lesions, less lateral or posterior in extent, were associated with not only fewer adverse effects but also greater symptom reduction.

A 2011 study is an example of a more recent use of capsulotomy in intractable depression. Twenty patients treated from 1992 to 1999 were followed for a mean of 7 years. At follow-up, 50% were responders. Neurocognitive and personality testing were not significantly different. Significant adverse effects were infrequent, and there were no deaths. A 2019 prospective study of capsulotomy for depression ($n = 10$) by a different group found a 60% response rate and no pattern of adverse neurocognitive events. The response was associated with changes in ventromedial but not dorsolateral prefrontal pathways on diffusion MRI.

Gamma Ventral Capsulotomy

Starting in the 1990s, radiosurgery has been used in intractable OCD for intractable OCD. The procedure which developed was ventral capsulotomy, placing two lesions (“shots”) in the ventral portion of the anterior limb of the internal capsule under MRI guidance using the Leksell Gamma Knife. A study reported in 2018 by Rasmussen and colleagues describes the largest cohort of gamma ventral capsulotomy (GVC) participants to date (*n* = 55), where the first patient had the procedure in 1993. Like almost all studies of lesion procedures, this was open-label. It showed a significant reduction in OCD symptom severity (a YBOCS severity drop of 35% or more) in 56% of the group. Patients also had significant improvements in depression, anxiety, quality of life, and global functioning.

Five-year outcome data illustrate the delayed nature of the response. The therapeutic benefit was achieved over 1 to 2 years and was essentially stable by 3 years. Full responses (YBOCS OCD severity improvement by >35%) developed in over half of cases by 2 to 3 years after surgery. Partial responses averaged approximately 10% at 2 to 3 years postop. Psychiatric adverse events included manic episodes during follow-up in 6% of patients, all of whom had a prior history of hypomania or mania; all improved after mood stabilizers were started. One patient developed substance dependence years after the procedure, and another developed a mild frontal syndrome which later improved. The most serious adverse effect after Gamma Knife ventral capsulotomy was radionecrotic cyst formation in 5% of the group, which in one case had severe sequelae. Cyst formation is a risk also associated with Gamma Knife radiosurgery for other indications, as is cerebral edema and headache (onset after months to years). And small asymptomatic caudate infarctions in 11%. In general, studies have shown no changes in personality and either stable or improved cognitive functioning following Gamma Knife anterior capsulotomy.

A controlled trial of GVC carried out at the University of São Paulo, Brazil is a rare example in the literature on ablative psychiatric neurosurgery. Sixteen patients with rigorously defined intractable OCD were enrolled; 8 received active GVC, and 8 received sham surgery in which they entered a specially constructed antechamber attached to the Leksell Gamma Knife. The groups were followed for 1 year, after which individuals in the sham group were offered actual surgery. There was no change in the sham group during the 1-year follow-up period. In contrast, two patients (25%) in the active GVC group showed reductions in OCD severity during the masked phase of 35% or greater on the YBOCS. Given the small sample, the effect reached the trend level of statistical significance (p = .54). In the group receiving active surgery first, five of the eight patients (62.5%) went on to respond during follow-up after the masked phase. Four of the eight patients who initially received the sham procedure later underwent the active procedure. Two of these later responded, for an overall response rate of 58% after active radiosurgery in the total sample. In this study, a longer masked sham period, which would have been optimal scientifically given the delayed nature of the response, was not chosen given the ethical concern that severely ill individuals not undergo unduly long follow-up after sham surgery.

Newer Methods: Laser Interstitial Thermal Therapy and High-Intensity Focused Ultrasound

More recently, given technologic advances in the use of real-time neuroimaging in targeting brain structures, a new technique, LITT (or laser ablation), has been used for capsulotomy. This procedure is a minimally invasive ablative approach using laser thermal energy transmitted via fiber optic catheters fed through cranial burr holes. In recent open-label research, responses were comparable to other capsulotomy techniques: McLaughlin et al. found 77.8% full responders (seven of nine patients) after LITT for treatment-resistant OCD. Adverse effects included transient apathy/amotivation postsurgery (two patients), hemorrhage (one patient), and persistent insomnia (one patient).

A different emerging technology, in this case, used to noninvasively create ventral capsulotomy lesions is MRI-guided HIFU, which utilizes high-power sonication to create targeted thermal lesions in neural tissue. HIFU can make targeted intracranial lesions without the need for burr holes or craniotomy. One group, Kim and colleagues, in South Korea recently demonstrated that 54.5% of 11 patients had >35% reduction in YBOCS OCD severity 2 years after the procedure, which was well tolerated. An issue in using this method is that adequate lesions are not made after HIFU in all individuals, based on factors including skull density which differ across individuals. Thus, in one study, while four of six OCD patients who had adequate lesions responded, 25% of those undergoing the procedure were excluded from the analysis due to inadequate lesions.

Subcaudate Tractotomy

Subcaudate tractotomy was introduced by Geoffrey Knight in 1964 as an early attempt to limit adverse effects by restricting lesion size compared to prefrontal lobotomy. Targeting the substantia innominata (just inferior to the head of the caudate nucleus), its goal was to interrupt white matter tracts connecting the orbitofrontal cortex and subcortical structures. The surgery involved placement of radioactive yttrium-90 seeds at the desired centroid, yielding lesion volumes of approximately 2 cc on each side. Subcaudate tractotomy has been used primarily in OCD and major depression. It has sometimes been used as a procedure subsequent to anterior cingulotomy when the latter has been judged to have a suboptimal outcome. Subcaudate tractotomy is now rarely done as a single procedure.

A 1975 study (predating MRI-guided surgery or modern psychopharmacology) reported follow-up data (at 2.5 years on average) for 134 patients (of an initial 208) after subcaudate tractotomy in a mixed patient population (OCD, depression, or anxiety disorders). The subset was chosen since adequate data, including structured interviews, were available. Global improvement was judged clinically meaningful in 50%, 68%, and 63% of those with OCD, depression, and anxiety disorders, respectively. Individuals with schizophrenia, substance abuse, or personality disorders did poorly. Adverse events typically included transient headache, confusion, somnolence, or disinhibition. Longer-term adverse effects included “mild” undesirable personality changes in 7%, seizures in 2%, and suicide in 3%.

In 1994, a review of 1,300 subcaudate tractotomy cases concluded the procedure enabled 40% to 60% of patients to lead normal or near-normal lives. The suicide rate was 1% versus 15% in a contemporary comparison group with major affective disorders. There were no deaths due to other causes in this series, and the seizure rate was comparable to that seen in previous reports. In contrast to the earlier report, the 1994 review did not find enduring personality changes. The investigators proposed predictors of positive response, including MDD diagnosis, sudden onset of symptoms, positive family history of psychiatric disorder, and previous positive response to electroconvulsive therapy. Physiologic responses elicited during intraoperative electrical stimulation of the target area before it was lesioned were also thought to predict better responses.

Limbic Leucotomy

Limbic leucotomy (also spelled leukotomy) combines subcaudate tractotomy and anterior cingulotomy. It was introduced by Desmond Kelly and colleagues in 1973. The lesions have typically been made via thermocoagulation or with a cryoprobe. Prior to MRI guidance, intraoperative stimulation was used to guide the placement of the lesions—eliciting autonomic responses was thought to mark the target. As for other procedures, limbic leukotomy has been used for OCD, major depression, severe anxiety disorders, and, less often, for otherwise treatment-intractable repetitive self-injurious behaviors or tic disorders.

An initial report of prospective outcomes in 66 patients reported global improvement, at a mean of 16 months of follow-up, in 89%, 78%, and 66% of patients with OCD, major depression, and anxiety disorders, respectively. A subsequent report found that 84% of those with OCD were improved at 20 months. Transient side effects included headache, lethargy or apathy, confusion, and lack of sphincter control. There were no reported seizures and no deaths; however, enduring lethargy was present in 12%, and one patient suffered severe memory loss due to improper lesion placement.

Much later, in 2002, Montoya and colleagues reported on 21 patients who underwent limbic leukotomy for OCD or major depression at Massachusetts General Hospital. Using stringent criteria, they reported that 36% and 50% responded, respectively, at a mean follow-up of 26 months. Another 2002 report described five consecutive cases that suggested that limbic leucotomy might be beneficial for patients with severe self-mutilation in the context of repetitive self-injurious, tic-like behaviors. A subsequent study from a different group of 16 patients with affective disorders found that 69% responded, 19% had a partial response, and 13% did not improve or became worse.

More recent reviews of limbic leucotomy have noted short-term adverse effects on memory, headache, hallucinations, extrapyramidal signs, perseveration, confusion/delirium, scalp infection, and urinary incontinence with lethargy and seizure (approximately 3%) adverse effects that have the greatest impact. Patients often had longer postsurgical hospitalizations as compared to subcaudate tractotomy or cingulotomy alone. Overall, the adverse effect burden of limbic leucotomy appears greater than those of other lesion procedures.

DEEP BRAIN STIMULATION

DBS for psychiatric illness is an old idea, although the devices, surgical and stimulation techniques, and theoretical models of relevant neurocircuitry, as well as how to define structural and functional networks, continue to advance. In 1948, Pool and colleagues used caudate nucleus stimulation in a patient with depression and anorexia, and there was a line of research by Heath and colleagues that included stimulation to “septal nuclei” in the 1950s and 60s. Modern DBS began 50 years after the earliest work when in 1998, Nuttin and colleagues described a case series of patients who received DBS initially based on the anterior capsulotomy target for intractable OCD, with positive results. The procedure involves the placement of small-diameter brain “leads” with multiple electrode contacts into subcortical nuclei or specific white matter tracts. The surgeon drills burr holes in the skull under local anesthesia and then places the leads, guided by multimodal imaging and stereotactic landmarking. Usually, this is done bilaterally. The patient is typically sedated but awake during surgery. Later, the “pacemakers” (an implantable neurostimulator or pulse generators) are implanted subdermally (e.g., in the upper chest) and connected via extension wires tunneled under the skin to the brain leads. Since various combinations of electrodes can be activated at adjustable polarity, intensity, and frequency, DBS permits a considerable range of ways one can modulate brain function. Thus, parameters can be optimized for individual patients. This might achieve improved efficacy and more favorable adverse effect profiles in comparison with ablation. The process of optimizing stimulation parameters for individual patients, typically performed by a specially trained psychiatrist in an outpatient setting, is quite time-consuming. Since device programming and troubleshooting need to continue indefinitely, providing DBS requires expert, attentive, multidisciplinary, and long-term follow-up. In cases where no beneficial settings can be identified despite extensive efforts, the electrodes can be inactivated, and device components may be surgically removed. The surgical risks of device removal include infection and hemorrhage, as for implantation. There are important psychiatric risks of device removal, which patients may view as the end of a “last resort” episode of care and could become despondent or suicidal as a result.

Here we focus on DBS for OCD, where there is regulatory approval in multiple countries (although health care reimbursement varies). There has also been considerable research on DBS for intractable depression, which has been reviewed in a number of places, including by Sullivan and colleagues (cited at the end of this chapter). Similarly, DBS for medically refractory Tourette syndrome is a focus on increasing interest and work; see the referenced article by Martino and colleagues for a discussion of the state of the art. There are multiple other potential uses of DBS in neuropsychiatric illness, ranging from addiction to eating disorders to others, which will not be further discussed here. We also do not discuss closed-loop or “adaptive” DBS, except to note that intriguing work in this area is ongoing and has the potential to not only advance this particular field but also to reveal physiologic signals underlying disabling symptoms in unprecedented ways. That, in turn, might inform advances in noninvasive brain-circuit–focused therapies, which could be applied to a vastly greater proportion of patients versus surgical approaches.

As noted, collaborative work in the 1990s led to the development of DBS at the ventral anterior limb of the internal capsule and adjacent ventral striatum (the VC/VS) for treatment-intractable OCD. A collaborative study by Greenberg et al. reported open-label data (*n* = 26); some later underwent masked DBS discontinuation. Across centers, 61% had a full response (≥35% YBOCS improvement), and 12% were partial responders (25% to 34% improvement). In the group as a whole, responses tended to stabilize after about 3 months of stimulation, although this varied across individuals. Cognitive functioning was not adversely affected by DBS. Adverse events included hemorrhage after implantation in two patients (~8%); in one of them, apathy resulted, which resolved over 3 months. One patient (~4%) had a single seizure intraoperatively without recurrence. One patient developed a superficial surgical wound infection that responded to antibiotics. In two patients (~8%), a DBS system wire broke, requiring surgical replacement. Complications due to stimulation itself or stimulation interruption were the most common, including four (~16%) patients with worsened depression or suicidal thinking similar to events in their presurgical course of illness. In three of them, this worsened depression occurred during a blinded crossover to sham stimulation. Mild hypomania, judged as stimulation related but nonserious, was seen in eight patients (31%). In all cases, hypomania was either reversible with a change in stimulation or resolved over days without a DBS parameter change.

In a study of DBS at an anatomical target closely related to the VC/VS, the nucleus accumbens (NAcc), 16 patients underwent 8 months of open-label treatment which included (as did the VC/VS study) exposure-based behavior therapy and ongoing pharmacotherapy. The open phase was followed by a double-blind crossover phase with randomly assigned 2-week periods of active or sham stimulation, followed by open maintenance DBS. In the open phase, 56% of patients responded. In the double-blind, sham-controlled phase (*n* = 14), YBOCS scores were significantly lower for active versus sham stimulation. The most prominent stimulation-related adverse was elevated mood or hypomania in 50% of patients, judged nonserious in all cases. One patient (6%) had a surgical wound infection, while five (31%) reported forgetfulness, and three (19%) reported word-finding difficulties. However, objective testing in this, as in other studies of psychiatric DBS, found either a lack of cognitive deterioration or improvement. This is unlike the situation in DBS for movement disorders, where stimulation at the subthalamic nucleus may be associated with cognitive decline in Parkinson disease.

A controlled crossover study investigated the effects of DBS at a different target within the general cortical–basal ganglia–thalamic circuitry implicated in OCD, the subthalamic nucleus. Of a total group of 16 patients, half were randomized to active DBS and half to sham stimulation, after which each group crossed over to the other condition in a double-masked fashion. There was a significant difference between active and sham DBS in favor of the active treatment. Adverse events included an intracerebral hemorrhage on device insertion in one patient (6%), leading to a permanent motor deficit in one hand, and infection leading to pulse generator removal in two patients (12%). One patient was described as having stimulation-related hypomania, and one with mania related to DBS. Both effects were reversible.

Most recently, there have been a number of relatively small-scale controlled trials of DBS for intractable OCD, focusing on targets including the ventral anterior limb of the internal capsule, the VS/NAcc, and the (also adjacent) bed nucleus of the stria terminalis. The studies have had different designs, including a sham stimulation–controlled “delayed start” or alternatively open-label stimulation optimization followed by masked stimulation withdrawal. Irrespective of these differences, this group of studies found improvement rates roughly comparable to each other, that is, above 50% “full response” with respect to OCD severity on the YBOCS. It is worth emphasizing that the YBOCS is “nonlinear,” meaning that at the most severe end (where all surgical candidates fall by definition), a relatively small change in score can mean a relatively large gain in symptom-free time, which is the single most important clinical feature related to improvement. Thus, YBOCS changes in groups of this type may underestimate actual improvement.

Major Depression

There is continuing research into DBS for intractable major depression. One line of work began with observations from functional neuroimaging pointing to the subgenual cingulate cortex as a node in circuits involved in the normal experience of sadness, symptoms of depressive illness, and responses to depression treatments. A small open-label study found that patients with unipolar depression refractory to four or more treatment trials improved after stimulation of white matter tracts adjacent to the subgenual cingulate cortex. A larger prospective trial had similar findings. However, a large industry-supported controlled trial of subgenual DBS was stopped early based on a “futility analysis.” The stimulation target continues to be refined based on updated hypotheses concerning which neural pathways, amenable to identification on diffusion MRI prospectively, might be most important to modulate.

Another line of research on DBS for depression was prompted by the VC/VS DBS OCD research discussed above and on observed antidepressant effects of anterior capsulotomy on which the VC/VC stimulation target was initially based. The OCD patients in both the lesion and DBS experience had high rates of comorbid depression, as expected in that population. Responders displayed rapid improvements in mood and motivation, which preceded reductions in core OCD symptoms. An open-label study of DBS at the VC/VS target for depression without comorbid OCD enrolled patients meeting a very high threshold for treatment refractoriness and found clinically significant antidepressant responses in roughly half of the patients. Induction of transient, reversible mood elevation, occasionally reaching the diagnostic threshold for hypomania, was the most significant adverse effect of active stimulation. However, similarly to the subgenual cingulate DBS industry-supported trial, an industry-led controlled trial of VC/VS stimulation for intractable depression was also stopped early due to futility, reflecting low response rates in both the active and sham stimulation groups.

CURRENT STATE OF PSYCHIATRIC NEUROSURGERY

Despite progress and the promise of advances in conventional medication and behavioral therapies, there remains a small proportion of individuals with intractable OCD, major depression, or other conditions who are potential candidates for neurosurgical treatments. These individuals remain very ill and chronically disabled despite sustained and conscientiously applied standard care. As with any treatment, the potential risks and benefits of psychiatric neurosurgery must be weighed against the potential risks and benefits of foregoing these approaches in individuals likely to remain burdened with severe illness and very poor quality of life. What remains true across eras in which stereotactic psychiatric neurosurgery has been applied is that half or more of carefully selected patients may show clinically meaningful benefit for a period of years after neurosurgeries, whether lesions or intracranial stimulation and that a subset might show outstanding improvement. Although data remain incomplete, and cases of attempted and completed suicide have continued to occur after psychiatric neurosurgery, these procedures might reduce mortality, as evidenced by data on comparative suicide rates. Nonetheless, patients who undergo and fail to benefit from these “last resort” procedures are at particularly high risk for completed suicide.

Given the current landscape, clinicians are faced with a number of issues when considering a particular clinical or research procedure for a given patient who might be judged a candidate for neurosurgery. The first, for OCD in particular, is consideration of a lesion procedure versus DBS. DBS may be acceptable to patients who would not choose to undergo lesion procedures, although the reverse is also true, given the long-term treatment context of DBS. Despite its advantages of reversibility and adjustability, DBS implantation carries risks and, importantly, requires that patients be treated by highly specialized teams willing and able to provide long-term care. The logistics and expenses involved, including inconsistent coverage by insurers, can represent significant barriers. In contrast, psychiatric care can be delivered in standard treatment settings after lesion procedures. However, although the relative risks of enduring adverse effects after psychiatric DBS remain to be clearly established, at this stage, ablative methods appear to carry a greater potential for them. Rates of adverse outcomes are relatively low when modern lesion procedures are performed by highly experienced multidisciplinary teams, something also seen with DBS for movement disorders, where there has been the most experience. This represents a particularly strong rationale for the referral of appropriate patients to expert psychiatric neurosurgery centers.

RESEARCH AND FUTURE DIRECTIONS

The best evidence on which one could base treatment recommendations would be adequately powered, long-term, prospective comparison studies using random assignment of individuals to different surgical methods. That remains unlikely to become available. As noted above, the small number of appropriate patients, the experience and preferences of expert centers for particular methods, and the preferences of patients themselves for one method over another are all impediments in this regard. In contrast, long-term follow-up studies, systematic reviews, and ongoing research pointing toward individualized predictors of response have occurred and should be encouraged.

An example is a 2015 systematic review by Pepper et al., comparing outcomes of anterior capsulotomy to those of DBS for OCD. A total of 170 cases were identified across 20 studies. DBS targets were the VC/VS or the closely related NAcc. After DBS (*n* = 62) there was a 40% decrease in YBOCS scores, while after capsulotomy (*n* = 108), YBOCS OCD severity decreased by 51%. There was a 9% higher likelihood of remission after capsulotomy than after DBS. The authors noted no overall difference in complication rates, although the pattern of complications was different (lasting adverse effects tend to be more common after capsulotomy). The follow-up period was very different: 19 months for DBS versus 61 months for capsulotomy, which may allow for further development of improvement after capsulotomy, and, conversely, might not allow assessment of how many DBS patients experienced device failures or were no longer receiving stimulation for a variety of reasons.

Another 2015 systematic review by Brown and colleagues, also based on observational data, compared outcomes of anterior cingulotomy to those of anterior capsulotomy for OCD. Ten studies involving 193 total participants were included; the capsulotomy dataset was similar to that in the review above. Mean follow-up was 47 months for cingulotomy and 60 months for capsulotomy. At the last follow-up, 41% were responders after cingulotomy, while 54% responded after capsulotomy. Serious or permanent adverse events, characterized as the number of events per procedure, was 5.2% across cingulotomy studies and 21.4% across capsulotomy studies, although in the latter, half of those events were attributable to very high-dose, multiple target Gamma Knife procedures (which no longer would be performed) across three patients. Excluding those, the rate of serious complications in the capsulotomy group dropped to 12.8%.

There are several key research directions as of this writing. One is the use of increasingly high-resolution structural and functional imaging methods that can assess changes in the relevant networks, for example, their connectivities, prospectively after lesion procedures to test and generate hypotheses about which brain network alterations are most relevant to therapeutic improvement and also to adverse effects. As is possible in studies of ablative methods, work in DBS can make use of multiple modalities of neuroimaging at baseline to test for morphometric, fiber tract, and local and network activity as individual predictors of outcomes. This is occurring as brain science advances toward an understanding that functional brain networks may be less segregated than previously thought and could represent a “mosaic” of functional networks where small differences in, for example, lesion or stimulation within a given individual could make a relatively large difference in clinical responses. Moreover, there is early but promising work in both intractable OCD and major depression, where electrophysiologic correlates of symptoms or clinically relevant behaviors are recorded and analyzed. Such advances could make closed-loop or adaptive stimulation a viable option, which could enhance symptomatic responses, patient function, and quality-of-life outcomes. That line of research could also lead to physiologically informed targeting of ablation in individual patients.

In summary, current neurosurgical treatment continues to represent a viable option for appropriately selected patients with severe and treatment-refractory illnesses. Evidence remains most robust for OCD. As evidence has accumulated, it has become increasingly clear that the patterns of risks, burdens, and benefits, while they overlap, are distinctly different for DBS versus ablation. Research intended to inform psychiatric neurosurgery is proceeding along a number of fronts. Neuroimaging techniques might be a potential aid in individual patient selection by predicting treatment response. Structural and/or functional neuroimaging might be used to tailor surgical interventions on an individual basis. Observations suggest that ablation or DBS might enhance the benefits of subsequent behavioral or medication therapies that proved ineffective before surgery. Both kinds of treatments are being studied in the context of an increasing focus on the neurocircuitry underlying both syndromic illness and dimensions of psychopathology. Insights gained from invasive methods have the potential to inform further development of noninvasive, circuit-based treatments for psychiatric illness, such as transcranial magnetic or electrical stimulation or low-intensity focused ultrasound, which, uniquely, promises to noninvasively modulate deep brain structures.

Child Psychiatry

34.1 Introduction and Overview

Caroly Sue Pataki, M.D.

UPDATES IN CHILD AND ADOLESCENT PSYCHIATRY

The past decade has demonstrated major advances in evidence-based knowledge in child and adolescent psychiatry, with investigation of new disorders and significant gains in modalities to provide effective treatments to youth. Efforts to link scientific advances and psychosocial insights to more individualized treatments for childhood psychiatric disorders have been met with increasing promise. Five new chapters are included in the child and adolescent psychiatry section of this edition of the textbook. These include Internet Gaming Disorder in Youth; Social Media and Youth; Gay, Bisexual, Transgender, Queer/Questioning, Intersex, and Asexual (LGBTQIA) Youth; Racism and Discrimination's impact on the health and well-being of Developing Children and Adolescents; Forensic Evaluations of Child and Adolescent Migrants.

Since the COVID-19 pandemic, starting in 2020, there has been an explosion of telehealth utilization to provide uninterrupted treatment to children and adolescents remotely. This necessity has led to an ability to provide treatment to youth in regions that are difficult to reach in person, as well as overcoming barriers of transportation. The success of telehealth over the past 2 years has reinforced the utility of this modality and will likely have a long-term impact on the options for providing psychiatric treatment to children and adolescents in the future.

Data from large randomized controlled studies and their follow-up over the past 10 years support the efficacy of medications, cognitive behavioral therapy, and especially their combination, for youth manifesting obsessive-compulsive disorder (OCD); anxiety disorders including generalized anxiety disorder, separation anxiety disorder, social anxiety disorder; and major depressive disorder (MDD). Those youth with the most robust positive responses within the first 3 months of treatment are the most likely to maintain these gains over the long term.

Genetic research, including genome-wide linkage scans seeking to identify gene loci, has focused on several childhood disorders, including attention-deficit hyperactivity disorder (ADHD), autism spectrum disorders (ASDs), Tourette syndrome (TS), and OCD. Neuroimaging studies have elucidated the brain development of typically developing children, as well as in children with psychiatric disorders. For example, neuroimaging studies have revealed that whereas total brain volume remains virtually stable after the age of 5 years, there are two dynamic processes continue through adulthood. These processes, synaptic pruning and myelination. profoundly influence cognitive and social decision making and behavior. Furthermore, neuroimaging studies have led to the conclusion that girls and boys differ in the timing of maximal gray matter volume and its normal decline after puberty, in that the process occurs about 1 year earlier in boys than in girls. A variety of neuroimaging techniques, such as magnetic resonance imaging (MRI), functional MRI (fMRI), diffusion tensor imaging (DTI), computerized tomography (CT), single photon emission computerized tomography (SPECT), and positron emission tomography (PET) have been increasingly employed to uncover both morphology and function of various parts of the brain to further understand childhood psychiatric disorders such as ADHD, mood disorders, OCD, and anxiety disorders, including post-traumatic stress disorder (PTSD).

The *Diagnostic and Statistical Manual of Psychiatric Disorders*, Fifth Edition Text Revision (DSM-5-TR), published in 2022 integrates the criteria for the childhood disorders published in in 2013 in the DSM-5, and makes some further modifications mainly for clarity in an effort to refine and match the criteria with available scientific evidence and expert consensus. It is well known that youth with the same psychiatric disorder, as defined by the DSM-5-TR, may present with heterogeneous symptom constellations. Diagnostic categories have played an important role in providing explanations of symptoms to patients, communication between clinicians, and providing a method for researchers to devise systematic studies. A limitation of a categorical (disorder) approach, rather than a dimensional (symptom or neurobiologic domain) approach in child psychiatric treatment research is that youth often present with overlapping symptoms of several disorders or present with multiple comorbid disorders. In fact, it is quite common for children to present with more than one psychiatric disorder. This clinical heterogeneity among childhood psychiatric disorders makes it a challenge to determine which constellation of symptoms will be most responsive to a given treatment.

An in-depth description of the clinical presentation, course, and treatment as well as updates on the scientific advances in childhood psychiatric disorders is presented in the following chapters.

CLASSIFICATION OF CHILDHOOD PSYCHIATRIC DISORDERS AND HIGHLIGHTS OF MODIFICATIONS IN DSM-5-TR AND DISORDERS UNDER CONSIDERATION

The DSM-5-TR provides a categorical classification system reflecting evidence-based and expert consensus on current childhood disorders. Children and adolescents who meet criteria for the same psychiatric diagnoses often present with heterogeneous clinical pictures. DSM-5-TR defines a psychiatric (mental) disorder as *a syndrome characterized by clinically significant disturbance in an individual's cognition, emotion regulation, or behavior that reflects a dysfunction in the psychological, biological, or developmental processes underlying mental functioning. Mental disorders are usually associated with significant distress or disability in social, occupational, or other important activities.*

The first edition of the World Health Organization's *International Statistical Classification of Diseases (ICD)* to contain a section for mental illness was the sixth (ICD-6). The first formal draft of a U.S. variant of this document, the DSM, was developed shortly thereafter, in 1952, by the Committee on Nomenclature and Statistics of the American Psychiatric Association.

Dennis Cantwell, MD, along with many psychiatric colleagues, was instrumental in advancing the classification of child psychiatric disorders through suggested revisions to the DSM in an effort to facilitate empirical investigation. These efforts were first realized in the development of the DSM-III in 1980. The DSM-III included explicit diagnostic criteria for each disorder, use of the multiaxial system, and a diagnostic focus on phenomenology rather than etiology. The DSM-5-TR does not include the multiaxial system; however, it allows for specifiers to denote important psychosocial factors.

Although both categorical and dimensional approaches have merit in describing psychiatric syndromes in youth, the DSM system uses only categorical criteria to identify psychiatric disorders. The overlap of behavioral and mood symptoms across multiple childhood and adolescent disorders made defining the boundaries challenging. In addition, it soon became evident that in more severely psychiatrically impaired youth, comorbidity is the rule rather than the exception.

Highlights of changes in childhood psychiatric disorders and diagnostic criteria first added in 2013 in DSM-5 and maintained in DSM-5-TR, published in 2022, include the following:

Autism Spectrum Disorder (ASD) was first added to the DSM-5 as a new disorder 2013, and maintained in the DSM-5-TR. ASD is characterized by core deficits in two areas: (1) social communication/social interaction, and (2) restricted pattern of interests, behaviors, or activities. ASD subsumes the following five pervasive developmental disorders contained in previous versions of the DSM: autistic disorder, Asperger disorder, childhood disintegrative disorder, Rett disorder, and pervasive developmental disorder not other-wise specified.

Social (pragmatic) communication disorder—a new disorder first added in DSM-5 is characterized by persistent deficits in the social uses of verbal and nonverbal communication, however, without a restricted pattern of behaviors or interests.

Specific learning disorder—new disorder to DSM-5 in 2013 and maintained in DSM-TR encompasses the previous disorders: reading disorder, mathematics disorder, disorder of written expression, and learning disorder not otherwise specified. Specifiers indicate which skills are affected.

Disruptive mood dysregulation disorder—a new disorder in the DSM-5 and maintained in DSM-5-TR characterized by children and adolescents with persistent irritability and frequent episodes of severe tantrums.

DEVELOPMENTAL PERSPECTIVE: IDENTIFYING THE EMERGENCE OF A CHILDHOOD PSYCHIATRIC DISORDER

Onset

Onset of a psychiatric disorder is a challenging concept in child and adolescent psychiatry because it is often difficult to pinpoint reliable landmarks for sufficient symptoms and impairment. Defining the onset of a childhood psychiatric disorder must include a balance between too narrow and too broad a set of diagnostic criteria. In other words, defining the onset of a disorder by a single impairing symptom might lead to the inclusion of a heterogeneous group of disorders, whereas inclusion of a rigid set of symptoms might exclude important subtypes. Age at onset of a childhood or adolescent psychiatric disorder is a variable of considerable importance because the emergence of a known constellation of symptoms at a younger-than-expected age might reflect increased vulnerability genetically or environmentally. For example, a younger childhood onset of major depressive disorder is associated with an increased probability of depressive disorders in first-degree relatives and implies an increased genetic vulnerability.

Onset of Child and Adolescent Psychiatric Disorders. The onset of a psychiatric disorder in a child or adolescent is often difficult to pinpoint. Investigations of age at onset of a psychiatric disorder can be applied to models of delayed onset of illnesses. Developmental failure (i.e., a lack of physiologic development within the nervous system at the appropriate time) is another model of delayed onset of a disease process.

A theory of delayed onset of a disorder, the two-hit model, hypothesizes that the emergence of a disorder is related to a “primary” genetic vulnerability triggered by exposure to a second event that may be environmental. For example, the rate of emergence of bipolar disorders increases markedly during adolescence, is maximal in young adulthood, and then gradually diminishes. One model to explain the emergence of a disorder with this distribution is a genetic predisposition (first hit) leading to vulnerability for the disorder and a second exposure, possibly the process of puberty itself or an adverse life event (second hit), that results in the emergence of the disorder.

Genetic anticipation is defined as the emergence of more severe forms of a genetic disorder in successive generations. This mechanism has been shown to contribute to the severity of pathology in a number of genetic disorders that are caused by mutations of DNA triplet repeat nucleotide sequences. Increases in repeat patterns of three nucleotides (e.g., GAC GAC GAC) increase the length of DNA sequences and result in pathologic genes. Triplet repeat expansion has been shown to be the mechanism of a number of genetic disorders, including Huntington disease and fragile X syndrome. Anticipation has been suggested as a possible explanation for increasingly severe psychopathology in successive generations in psychiatric disorders. The investigation of possible molecular bases of anticipation in psychiatric disorders, such as the increased density of genetic triplet repeat expansions shown in Huntington disease and fragile X mental retardation, is on the horizon.

Neuroimaging Studies in Child and Adolescent Psychiatry

Neuroimaging studies over the past 10 years have provided increased evidence of the dynamic changes that occur in developing brains. Neuroimaging has further increased an understanding of multiple childhood psychiatric disorders including ADHD, mood disorders such as MDD and bipolar I disorder (BP-I), anxiety disorders, OCD, PTSD, TS, childhood-onset schizophrenia, substance use disorders, feeding and eating disorders, ASD, and specific learning disorders including dyslexia. For example, recent studies have found that methylphenidate, the first-line treatment for ADHD, changes frontal–striatal activation in pediatric patients with ADHD, with greater prefrontal cortex (PFC) and striatal activation as measured by fMRI demonstrated in ADHD patients.

fMRI, in studies by Swartz and colleagues, has shown, for example, that children with ASDs have hyperaroused amygdalae leading to deficits in habituating to a variety of stimuli including sounds, sad faces, and certain tactile feelings. This may contribute to the typical sensory sensitivities in children. Singh and colleagues employed fMRI to show that adolescents with bipolar disorder have less activation in superior frontal brain regions after a negative experience, compared to healthy adolescents, which may be indicative of deficits in executive control over emotional decisions. Child and adolescent brains have been described by clinicians and researchers as “works in progress,” with a series of predictable patterns of biologic processes that extend into and beyond adolescence. The neuroimaging work of Giedd, Rapoport, Rosenberg, Castellanos, and others has revealed the typical wave of high production of gray matter among developmentally normal adolescents emerging just before puberty. Furthermore, investigations have documented the links between the pruning and myelination processes in various sites in the brain and the subtle increases in social and emotional problem-solving abilities that typically emerge in later adolescence. Other investigations have identified areas of the brain targeted in children who learn first and second languages early in life. fMRI scans have determined the spatial relationship of language centers in children who have first and second languages. In such children, both language centers appear in the same cortical region whereas when a second language is acquired in adult life, the new language center is not represented in the same cortical region as the first language. MRI studies have also provided evidence that adolescents process emotional stimuli differently than adults. Using fMRI and presenting pictures of faces depicting various emotions, Yurgelun-Todd and colleagues showed that in young teens, who typically have difficulties with the task, the amygdala (a brain center for fear reactions) is activated during the task of identifying the emotions presented; whereas in older teens, who perform better on the task, the frontal lobes are more active in the process of identifying emotions in the stimuli. There were also additional findings indicating that language tasks correlated with activation of temporal lobes in young teens and of frontal lobes in older teens.

GENE X ENVIRONMENT INTERACTIONS: RISK AND PROTECTIVE FACTORS

There is a convergence of evidence regarding the interactional effects of genetic vulnerability and environmental events on the development of many psychiatric disorders. Much research has focused on the alleles of the serotonin transporter gene and sensitivity to adverse events and stress. The impact of age and developmental stage that a stressful event is experienced adds another factor to the equation, and finally, positive relational and environmental variables may increase resiliency. Risk factors include all variables that increase the probability that a given child or adolescent will develop psychopathology. Protective factors decrease the risk of developing psychopathology. Demographics, psychosocial factors, biologic factors, genetics, family environment, and external environment interact to produce risk and protection from psychiatric disorders. Rarely can a single risk factor account for the entire variance between the emergence and inhibition of a psychiatric disorder. Thus, the study of psychiatric risk is complicated and multifactorial. Risk factors often studied for influence on the emergence of psychiatric disorders among children and adolescents include family history of psychiatric disorders, social class, intellectual function, adverse life events, temperamental factors, and the quality of family and peer relationships. Developmental delays, child maltreatment, and high levels of family conflict increase the risk of psychiatric disorders. Protective factors that have been identified and studied include individual temperamental predisposition, positive family relationships, and success experiences academically and socially.

INTERVENTIONS FOR PSYCHIATRIC DISORDERS IN YOUTH

Interventions to address psychiatric symptoms and disorders in youth include clinical, targeted, and universal interventions.

Clinical interventions provide treatment to a family with a child or adolescent identified as having a psychiatric problem. Psychosocial, psychopharmacologic, and other environmental interventions can be compared with a placebo condition and with each other to assess efficacy. Approximately one-half of families who begin psychiatric treatment terminate prematurely, thus, the nature and delivery of the treatments also merit investigation.

Targeted interventions are designed for children identified as at increased risk of a psychiatric disorder but whose families are not seeking treatment. Children at risk may be identified either by an external factor, such as a family characteristic (e.g., offspring of a parent known to have a psychiatric disorder) or through a behavior (e.g., defiance or aggression in the classroom). A given child may be monitored or receive a psychosocial intervention on the basis of the risk factor—whether psychiatric disorder is already present or not;

however, these interventions may not be welcomed by the family, or threshold for interventions may not be correlated with a clinically relevant situation.

Universal *interventions,* also termed *primary prevention,* are received by all children and families within a specific geographical distribution. They may occur throughout a targeted school or community or on a citywide, statewide, or national basis. This strategy obviously reaches more children than any other method of intervention, but questions arise about the benefit and need of the intervention for the population at large, as well as the cost–benefit ratio.

Study of the risk factors and protective factors is leading the field to develop the most effective combination of prevention strategies for children and adolescents. More effective treatments are being investigated in order to match the treatment to the individual. Future goals include mitigating risk factors, enhancing protective factors, and when prevention is not possible, to provide efficacious treatments.

34.2 Child Development

GABRIELLE SHAPIRO, M.D., D.F.A.A.C.A.P., D.F.A.P.A., ROBERT J. JAFFE, M.D., ALEXANDER KOLEVZON, M.D., AND TRESHA A. GIBBS, M.D.

Imagine an infant reciting Shakespeare, a toddler calculating trigonometry angles, or an 8 year old driving to grade school each morning. The thought of children performing mundane adult tasks highlights the obvious: humans are born with a very limited skillset and develop a more complex one over time. In essence, development is the acquisition of new skills and the multiplex reactions to these additions. Whether it is the capacity to walk, talk, empathize, or think about the future, suddenly, a capacity is there that previously was not. At no time in life is the explosion in newfound possibilities more pronounced than in early childhood, the focus of this section.

With a basic understanding of development, clinicians of every discipline can benefit their patients. Pathology can frequently be traced back to childhood, offering clues as to its inception and psychological sequelae. Often, adult patterns of symptom presentation or behavioral interaction with the environment mimic patterns from childhood.

Until the 1600s, children were viewed as “small adults” and expected to work and socialize in an adult manner. Children were sources of cheap labor during the Industrial Revolution. This era’s end, coupled with compulsory school laws in the United States, meant that by the early 20th century, the vast majority of children were attending schools. John Dewey was essential in viewing schools as a vehicle through which childhood development could be fostered. G. Stanley Hall formally studied children and adolescents and blazed a trail for the relatively recent surge in psychological theories by Sigmund Freud, Erik Erikson, Jean Piaget, and John Watson, to name a few.

Though the field remains ripe for further exploration, some critical concepts have emerged over the past 100 or so years. Normal development can be conceived of as what a typical child will go through in an average expectable environment. This section will highlight the ages when different changes are typically seen. It is imperative to understand that each new advance has a range of when its existence should be expected. Significant lags are thought of as developmental delays (with the exception of premature babies), whereas marked abnormalities in development are developmental disorders.

There is a debate as to whether development is a continuous or discontinuous process. What is clear is that the direction of the curve is not always positive, as there is a normal degree of progression and regression. It is normal during the acquisition phase of new skills for them to come and go. An example is a fluidly speaking 3 year old who, upon the birth of a younger sibling, will revert to baby talk. This is distinct from a frank loss of a solidified skill, a symptom which should always prompt inquiry.

Current research offers evidence that the mechanism for growth comes from the interplay of genetics and the environment. Though the relative contribution of each remains an area of debate, this transactional model has become the established paradigm. Genetic background primes an individual and provides potential, but can be altered positively and negatively based on environmental stimulation. Identical twins reared in the same household do not develop identical personalities. There is evidence that children shape their environment and elicit different responses from their environment, affecting how they develop. Some aspects of development are more genetically determined, whereas the environment may play a greater role in others. When pertinent, this section will highlight relative contributions.

This chapter will cover nine areas of development from birth through adolescence. The domains of brain, language, cognitive, social, emotional, motor, sensory, gender, and psychosexual development will each be addressed. Developmental lines are also interdependent, maturing on their own yet influenced by one another. For example, language fosters advances with emotional and social development.

Finally, the scope of this chapter is on normal childhood development only. Clinical correlates will be interspersed throughout to highlight the importance of understanding normal development in practice. There is also a comprehensive master table (Table 34.2–1) arranged by age on one axis and developmental domain on the other. This is intended as a quick reference to identify skills typically developed at a certain point in time or to follow one domain longitudinally.

BRAIN DEVELOPMENT

Unlike some other species, humans are born with an immature central nervous system (CNS). An infant is entirely dependent on others and is governed by innate reflexes, yet in time becomes a creature capable of complex cognitive, social, and emotional capabilities and remarkable physical and verbal skills. How does one go from someone who cannot hold his own head up to an athlete who can sense his orientation in space and manipulate his body accordingly? This section will focus on the physical changes to the brain during infancy and childhood which allow for all the capacities described in the rest of the chapter.

Table 34.2–1.
Child Development Resource Table

Periods:		Gestational–Infancy: 0–2 Years				Early Childhood (2–5 Years)			Middle Childhood (5–11 Years)			Adolescence	
	Theories	0–2 Months	2–7 Months	7–12 Months	1–2 Years	2–3 Years	3–4 Years	4–5 Years	5–7 Years	7–9 Years	9–11 Years	11–14 Years	14 Years on
Emotional development	(Integrated theory) Acquisition of basic emotions	Stage 1: Infant has innate emotions and emotional responsiveness—emotions are available and easily stimulated at birth			Stage 2: Self-conscious emotional reactivity	Stage 3: Connecting emotion with effects; emotional self-awareness			Stage 4: Develops an emotional responsiveness to the feelings of others				
	Emotional skills	Touching evokes love, loud noises evoke fear. Restrictions evoke rage. The brain pathways for the forming of emotions begin to develop	Emotions begin to become self-regulated as the brain pathways of emotion grow	Self-regulation of emotion continues to develop	Shame, pride, envy, and embarrassment appear. Displaces onto other children	Understands the sources of many emotions and begins to develop techniques for regulating emotions and expressing them Begins to identify with adults as a coping mechanism			Displays ability to react to the feelings of others, indicating a heightened sense of awareness and empathy				
	Emotional behavior	Infants have a "social smile" in response to human voices. They display the ability to respond to emotions of others	Begin to laugh and display more control over smiles. Anger is able to be shown as well	Ability to induce responsiveness increases	Begins to display empathy, as seen by expressions of feeling. The infant enjoys attention and approval and likes to play alone and next to peers	An increase in understanding leads to increased empathy. Self-regulation increases and the child becomes more responsive than reactionary. Aggression develops as a competition and by the age of 5, the child exhibits sensitivity to criticism and compassion			Until the age of 6, ego rules. At 7, empathy transforms into altruism, and the superego dominates				
Social development	John Bowlby's attachment theory	Preattachment (0–6 weeks)	Attachment making (6 weeks to 8 months)	In month 8, clear-cut attachment begins to develop >> stranger anxiety		2 years on, reciprocal relationships begin to develop							
	Margaret Mahler's attachment theory	Autistic phase (0–6 weeks)	Develops a symbiotic relationship with the caregiver (6 weeks to 8 months), and the beginnings of differentiation	Differentiation continues	Rapprochement (18 months to 2 years)	The development of consolidation and individuation							
	Robert Selman's stages of perspective taking						Level 0 (years 3–6): Beginning at age 3, child recognizes that the self and others can have different thoughts and feelings, but frequently confuses the two. (undifferentiated perspective taking)		Level 1 (years 5–9): After age 4, can understand social information; can understand that different perspectives may result because people have access to different information. (Social-informational perspective taking)		Level 2 (years 7–12): Begins to exhibit self-reflection. Now aware that they have ideas and attitudes, they look to friends to guide their self-discovery. Child can understand other's perspectives; can "step into another's shoes" to view their own thoughts, feelings, and behavior from the other person's perspective. (Self-reflective perspective-taking)	Level 3 (years 10–15): Can understand how the self is viewed from the perspective of a third-party; Progression from two-party situation. (Third-party perspective-taking)	Level 4 (14 to adult): Individuals understand that third-party perspectives are influenced by larger societal values. (Societal perspective-taking)
	Erik Erikson's social stages (psychosexually influenced)	Stage 1: Crisis: Basic trust vs. mistrust Virtue: Hope			Stage 2: Crisis: Autonomy vs. shame and doubt Virtue: Will		Stage 3: Crisis: Initiative vs. guilt Virtue: Purpose		Stage 4: Crisis: Industry vs. inferiority (6–11 years) Virtue: Competency			Stage 5: Crisis: Identity vs. role confusion Virtue: Fidelity, ability to live by society's standards and expectations.	
	Social behaviors	Infant acknowledges the caregiver as "different," recognizing caregiver's smell, voice, touch	Infant is able to differentiate self from caregiver and begins to manifest separation anxiety		Child revises constancy of caregiver and develops trust based on caretaker's ability to provide	Child begins to display independence, separating from the caregiver when given clear goals. Parents and caregivers help children develop a sense of autonomy by allowing the child to make choices	Child begins to assert their power and control over the world through directing play and other social interactions. By making comparisons to their peers, children develop a sense of purpose	Child begins to understand different perspectives	Continues to understand foreign views and preferences	Through social interactions, both at school and home, child begins to develop a sense of pride in their accomplishments and abilities. This helps develop a sense of competency	Although truly beginning at year 7, the child's ability to get motivation from others continues to develop from years 9–11	Can understand the point of view for third party, and from this understanding develops a secure personal identity and desires independence	Understands personal values and goals and can see issues through social value context
Psychosexual development	Freudian psychosexual stages	Oral stage			Anal stage		Phallic stage		Latency stage			Genital stage	
	Gender identity				Gender labeling and beginning of gender stability	Gender is usually fixed	Gender consistency			Gender constancy			
	Gender role				Stereotyping begins to appear	Emerges		Consolidates	Stereotyping fixed but becomes less rigid with increases understanding	Child looks to social cues to recognize gender			
	Gender relationship				Sex not an issue with peer choice	Sex play common	Same-sex peers favored			Increased masturbation and heterosexual play		Sexual activity begins	
	Psychosexual skill	Ego directs sucking needs			Child labels stereotypes through objects: "girls like pink" (1–1.5 years). Child can identify the sex of self, a picture, or other children by using clothes, toys, hair, activities, as proxies (1.5–2.5 years). Child lacks control over bowels	Child knows that gender label is a part of self but does not see it as constant. I.e., "I can't do that or I'd be a girl"	The child's id transferred to genitals and begins to view activities as related to gender and not causing gender. At this point, gender consistency develops, the child understands gender cannot be changed by objects or activities		Superego consolidates, and gender constancy develops, gender is constant regardless of clothing or behavior			Sexual activity increases	
Moral development	Piaget's stages of moral behavior related to cognitive phases							Egocentric stage (preoperational cognitive)		Incipient cooperation (7–11)			
	Piaget's two-stage theory of moral judgment (cognitively based)							Heteronomous morality: Moral realism: morality imposed from the outside morality comes from an authority figure and disobeying the rules results in immediate and severe punishment (immanent justice). Rules are fixed, divine like, view a large amount of accidental damage as worse than a small amount of deliberate damage (no concept of motive)		Autonomous morality (moral relativism): Rules no longer come from a divine-like source. Child can negotiate rules with peers (concept of reciprocity). Child is able to account for motives. Punishment becomes restitution vs. retribution. Child begins to argue about punishment because they understand justice is imperfect, punishment should be adjusted to crime			
	Kohlberg's six-stage theory of moral reasoning (cognitively, socially, and emotionally influenced)							Preconventional level: Judge the morality of an action by its direct consequences		Stage 1: (Obedience and punishment driven): Bases moral decisions on fear or self-interest. Stage 2: Relativistic orientation (self-interest driven). Child develops a concern for fairness and seeks rewards obtained by bartering "If I do my chores, what's in it for me?" (sees morality as rules for society's order). Stage 3: (social consensus determines good intentions): Tries to live up to societal notions of good and bad. Conforms to societal norms. Stage 4: (Social order obedience driven): It is important to obey the laws of system in order to maintain a functioning society. Teen and adult morals replace the preoccupation with what is "fair" for the individuals to what is necessary for society's needs; social conscience		Stage 5: Sees laws as social contracts. What is good for society is paramount Stage 6: Develops universal ethics and focus on fairness and justice. Recognizes others' moral standards	

	Freud's concept of superego as conscience (psychosexually influenced)									With the resolution of Oedipal complex, the superego forms with guilt and shame as boundaries. Development of conscience	
	Gilligan's sex theory of moral development (cognitively and psychosexually influenced)	Agrees with Kohlberg								Stresses that girl's ethical goals, which are different from boys, focus on compassion, relationships, and responsibilities. Boys' ethical goals are more focused on rationally committing to moral ideals of justice	
	Moral skills	Sense of rightness is limited to the self >> never having been hungry, the baby feels hunger is wrong. Never having been isolated, baby knows that unresponsiveness to touch is wrong. As a toddler, the child begins to observe the behavior of others. Cannot judge "right" and "wrong." The child must negotiate between what others say is wrong and what they want.						Self-control develops and the ability to relate behavior to morals begins to form. Guilt appears		Child's self-control improves. Child understands motives role in morality. The principles of the child's parents are internalized and empathy develops. Moral principles become more refined as an abstract concept of morality is formulated. The child becomes better at self-monitoring morality and empathy and cognitive moral integration occur	Altruism develops. The morals of peers are considered and individual rights are emphasized. The moral goal is to be fair to the self and others. Laws are mutable
Cognitive development	Piaget's stages of cognitive development	**Sensorimotor stage:** Object permanence (8–9)				**Preoperational stage:** Egocentrism Symbolic play Animism				**Concrete operational stage:** Conservation Reversibility Seriation	**Formal operational stages:** Abstraction Deductive reasoning
	Cognitive achievements	Recognizes faces (1st 2) Sleeps 16–18 hours, 2 naps	Eye-hand (4)	Hand/hand transfer (6–8) Self from caregiver (8)	Uses a cup (12) Follows directions (12) Sleeps 15 hours, 1 nap Names things (18–24) Knows items use (18)	Finds hidden items (24) 2-step instructions (24) 4-block towers (24) Copies straight line (24) Sleeps 13–14 hours	Copies circle (3) 6-block tower (3)	Time (4) Numbers/counting (4) Colors (4) Copies square (4) 4-limb body (4) Sleeps 12 hours, no naps (4) Theory of mind (4.5)	Copies triangle (5) Prints letter (5) Reading	Memory Problem solving Logical	Abstraction Adult sleeping patterns
Physical development	Language achievements	Cries (birth)	Coos (3–4)		First words (12) Combinations (18)		Tone and inflection 14,000 words	Most expressive language attained words fully understood			
	Perceptual achievements	All senses are activem Can recognize mother's voice Can see patterns, shapes, and contrast	Eye tracking (2) Stereopsis (3) Follows 180 degrees (4) Monocular depth (6–7)	Near adult visual acuity (8)		Full hearing (24) Intermodal perception develops	Intermodal functions become well developed		Adult vision (6)		
	Motor achievements	Reflexes (birth)	Supports head (2–4) Rolls over in both directions Sits unsupported (6–7) Pat-a-cake (6–8)	Crawls (8–9) Pincer grasp (9) Stands (9–10) Cruises (10–12)	First walking steps (12) Points (12) Beginning of scribbling Eats/drinks (18)	Runs/kicks/throws/jumps (24) Laterality appears	Rides tricycle (3) Daytime continence (3)	Holds pencil (4) Obtains full postural control	Hand preference (5) Nighttime continence (5–7)		

There are two important and related concepts affecting development: *critical periods* and *plasticity.* Critical periods are windows of opportunity for growth in certain areas. This window offers an opportunity for tremendous gains but is also vulnerable to disruption. For example, the first few years appear to be important for language, in particular, the first year for a perceptual map of phonemes. Plasticity enables the ability of one part of the brain to compensate for another. An example is the primary auditory cortex in congenitally deaf individuals which assists in processing visual and somatosensory stimuli.

Early in life, there are many changes occurring within the brain. Along with the rest of the body, the brain is growing substantially during the first few years. By age 5, it has tripled in size and is at 95% of its adult mass (1.2 kg for adult women and 1.3 kg for men). Growth occurs bottom-up in a caudocranial manner with the pons, medulla, and spinal cord ahead of the cerebellum, which is ahead of the cortex. This explains why infants rely on reflexes and instincts and lack coordination.

Histologically, the adult brain consists of billions of neurons configured into trillions of synapses. Early on it is a hotbed of activity. Neuronal *proliferation* and *differentiation* explode in utero and continue into the first year of life, particularly in the cortex. Though neurogenesis slows and was previously thought to halt, recent evidence has shown that two areas in adult brains possess the ability for new neurons, the subventricular zone and hippocampal dentate gyrus. These newly formed fetal and infantile neurons must get from their place of origin to their destination, which they accomplish in a task called *migration.* This journey is what lays down cortical columns and continues through the first 6 to 7 months of life, with the later neurons settling in the cortex. Once the neurons have reached their destination (and in certain cases even during migration), the cells experience dendritic and axonal outgrowth. This extension is particularly heavy during the first year and continues over the following 18 months.

The settled and grown neurons rapidly interact with one another with an explosion of new synapses during the first 2 to 3 years of life. By age 2, the toddler has roughly twice the number of synapses an adult will have. This number gets reduced as the child's synapses are *pruned* from 18 months to age 20, with the majority occurring between 7 and 15 years. During this process, the brain becomes more energy efficient, strengthening the connections that are needed while ridding itself (and the metabolic demand) of those that are not. Just which synapses are deemed necessary is a direct reflection of one's environment, a nature–nurture interaction which is fundamental to brain development.

To communicate with each other, the nerve cells need receptors and neurotransmitters. Serotonin appears first, followed by norepinephrine and dopamine, with acetylcholine and GABA produced later in fetal life.

Finally, the neurons become myelinated from birth to adulthood, a process of insulation which increases transmission speed. In general, *myelination* occurs first in the spinal cord and lower brain, with the cerebellum fully myelinated by age 4, the corpus callosum at 8 to 12 years of age, and the cortex from age 10 into young adulthood.

The manner in which these brain changes occur is a result of complex interactions between genes and environment. Biologically, genes initiate the process of brain development through organizer genes and homeoboxes such as *Sonic hedgehog, Delta,* and the *Hox* genes among many others. The endocrine system is also involved with insulin-like growth factor (IGF) and thyroid hormones playing roles. Environmentally, illnesses and toxic exposures can alter development. Diet and nutrition is thought to have an effect, as industrialized nations demonstrate faster growth than do developing ones. For example, an increase in docosahexaenoic acid may be linked to greater visual acuity. By kindergarten and even earlier, some children from disadvantaged backgrounds have been shown to lag behind in language and vocabulary and may have heard 30 million fewer words in the home. Neglect in infancy has been linked to a significantly reduced midsagittal area of the corpus callosum. Clearly, genes alone do not account for brain development.

Genetic programing allows for brain development so that the infant can learn new skills. These capabilities facilitate interactions with the environment, which then precipitates further genetic modification. For example, motor skills afford one the chance to throw a ball and learn what happens to it. Repetition stimulates the same neural pathways, strengthening the synapses. Neurotrophins and prostaglandins affect synaptogenesis and long-term potentiation, a process that underlies learning and memory. Underuse of a neuronal pathway due to lack of exposure leads to its pruning and atrophy, mediated by genes. In short, genes lead to abilities which feedback and control other genes, affecting synapses and pathways. Thus, both the skills governed by genetics as well as the environment in which they evolve are integral to development.

LANGUAGE DEVELOPMENT

Language is so essential and omnipresent in everyday life, it is hard to imagine that it does not exist at birth. Though the ability to *communicate* is present from day one, language development is a process that takes years to develop. Speech delay is a common cause for clinical presentation, and language delays may be associated with later psychiatric comorbidities. Moreover, an undiagnosed speech delay is present in patients presenting for other reasons. Therefore, an understanding of normal language development is indispensable for all providers.

The development of language begins in utero, where a fetus has been shown to recognize its mother's voice. On delivery, an infant clearly lacks the ability to speak, but yet still requires a way to demonstrate needs. This is achieved through facial expressions such as cries. An attuned parent can often tell what a baby needs (such as a feeding or diaper change) based on the particular type of cry. Though the exact timing of each step may differ, the overall process is quite constant. At about 3 to 4 months, typical infants make cooing (vowel) sounds followed by single-syllable consonant babbling. These are learned by imitating others and carry no meaning at this age. Repetitive vowel–consonant sounds (such as mama) may appear, but without meaning these are not considered first words. Meaningful words are produced at about 12 months, with single words intended to convey entire phrases. It is not unusual for words to come and go at this stage, and loss of a spoken word should not be cause for alarm. At 18 months, word combinations appear and about 25% of words are intelligible to strangers. At 24 months, there are about 300 words, 50% of which are intelligible. By 30 months there are 500 words. At 36 months, 75% are intelligible to strangers.

Grammar develops significantly from months 20 to 36. As children learn the rules of speech, incorrect verb tenses are common ("I throwed the ball"). The same child may have used this correctly in the past, which likely reflected an imitative phrase rather than a novel one, and is considered normal. By age 4, most expressive language is developed and appropriately used. Nearly 100% of words should be intelligible to strangers, even though pronunciation mistakes may be present. Over the next 2 years, children are able to connect sentences with one another logically. At ages 5 to 6, language centers slow their development, highlighting the importance of early language and the challenges of learning a second language later in life.

From a theoretical perspective, Noam Chomsky emphasized the universality of linguistic structure and that all humans develop the ability to understand and produce language. This stands in contrast to a behavioral theory of language, championed by B. F. Skinner. Skinner believed that children imitate others and have their language reinforced through the environment. Factors such as large family size and lower social class correlate with later development and fewer words. Expanding on these environmental variables, the quality of verbal stimulation plays an important role. Hearing words from reading is more effective than just hearing spoken words; significantly more “unique words” are perceived through books, likely exposing children to words they would not otherwise encounter. Recent fMRI studies show that children with a higher reading exposure had greater activation in the left parietal–temporal–occipital association cortex, integrating the auditory with the visual and potentially stimulating imagery and narrative comprehension.

A 24-month-old boy is referred from the pediatrician for severe behavioral outbursts. Upon taking a history, you discover that he only knows about 25 words and cannot make word combinations. You astutely hypothesize that the tantrums are the manner in which this child is expressing himself, and aim to identify the reason for the speech delay. Your differential includes hearing and vision difficulties, and vision and hearing tests are ordered. Deficits in other areas are explored for signs of a broader developmental delay including intellectual disability and autism spectrum disorder. Environmental contributors such as neglect or trauma must be ruled out. An auditory processing disorder is also a possibility. Finally, you conclude the delay is due to a speech or language learning disorder. A speech and language referral helps identify the nature of the delay and breaks speech down into further subcomponents: articulation (pronouncing sounds), syntax (the arrangement of words in a sentence), semantics (meaning of words), and pragmatics (appropriate social use of words). With speech therapy, the child makes linguistic gains and his behaviors subsequently improve as he now has other means to regulate and express himself.

COGNITIVE DEVELOPMENT

Cognition can be conceived of as what happens to sensory information once it reaches an individual. How this occurs is substantially more detailed and involves perception, understanding, memory, learning, reasoning, problem solving, and language. A discussion on cognitive development would be incomplete without mentioning *Jean Piaget.* He proposed four stages of cognitive development, with changes occurring through *assimilation* and *accommodation.* Assimilation, he argued, is taking in new information and fitting it in with an existing understanding, or *schema.* It is fitting new data into old ideas. This contrasts with accommodation, in which the new experience or sensory data causes the old schema to be altered so that it is in accord with this new information. For example, a child has an understanding of a tree, which is comprised of a trunk and branches. In the summer when leaves appear, the basic concept of tree remains the same but it has expanded to include this new knowledge. Later on, the child encounters a bush and calls this a tree as well. The child is taught the differences between a bush and a tree and a new bush schema is formed. Though parts of Piaget's theories have come under question, he added tremendous insight into how children think differently from adults. This has consequences for everyone interacting with children, and is especially noteworthy for those in the educational and health care systems. Given his significance to the field, this section will be structured around Piagetian stages.

The first of Piaget's stages is *sensorimotor,* occurring between birth and approximately age 2. As the name implies, at this stage, the infant is mostly limited to sensory information and simple motor responses. Within 2 months, the infant can pay attention to faces and even recognize them. They can follow things with their eyes. By 4 months, there is eye–hand coordination, as the infant can reach for something he sees. Recognizing familiar faces and important objects improves and extends to greater distances. At 6 months, they show curiosity for things out of reach, and once within reach, they tend to put them in their mouths. Eye tracking further develops over the next few months, as the infant can even follow the path of something as it falls. Picked-up objects can be transferred from hand to hand smoothly. At 9 months, peek-a-boo is a particularly fun game, notably because at this age, the infant is grappling with *object permanence.* To an infant lacking this skill, anything that cannot be perceived cannot exist. By the age of 1, there are clear signs that schemata are forming and are being used. A 12 month old typically can follow directions and use things correctly, such as a cup. These schemata strengthen and broaden over the next 6 months and at 18 months, they often clearly show knowledge of what a typical item is used for, such as a brush. As schemata are forming, a sense of humor can be seen when these expectations are playfully breached. Following simple instructions such as “sit down” implies an ability to understand language and know what to do with it. This implicates gains in memory and learning. By the age of 2, the individual can find hidden items, clearly demonstrating the achievement of object permanence. Make-believe games begin to take on a pleasurable role. Rudimentary organizational skills are demonstrated by sorting shapes and colors. Two-step instructions can be followed and four-block towers can be built.

The second stage Piaget described is *preoperational,* ranging from about 2 to 7 years of age. Symbolic play is a key feature of this time period. Pretend play and make believe, role-playing, and symbolization (such as a stick representing an airplane) appear. A hallmark of this stage according to Piaget is that toddlers exhibit *egocentrism,* meaning they lack the ability to take another’s point of view. Children in this stage lack the understanding of *conservation.* The classic example is if equal amounts of water are poured into a tall skinny glass and a short wide glass, those who have not mastered conservation yet will say the tall skinny glass has more water in it. This skill develops from ages 6 to 11 and may differ for various units of measurement.

Clinical Correlate

With egocentrism, children cannot take on another’s point of view and are susceptible to misattribution. This normal stage in development leaves one vulnerable should a major stressor occur. For example, loss of a parent, divorce, or terrorist attacks demand explanation, and typical children with egocentrism are likely to blame themselves for the event. Though with age they may cognitively realize the situation was not their fault, the initial memory and experience was recorded in that way and guilt and self-blame may be present. Whether treating a child in real time or an adult decades later, recognizing where the patient was developmentally at the time of tragedy is paramount for processing.

At age 3, children can copy a circle, complete three- to four-piece puzzles, and build a six-block tower. By age 4, they can understand the idea of same and different. They can start to understand time, begin to understand numbers and counting, draw two- to four-limbed bodies, name colors, and copy a square. At 5, they can count to 10, draw six-part bodies, copy a triangle, and start printing some letters.

The third Piagetian stage is *concrete operations,* from roughly ages 7 to 11. Order, rules, and organization are hallmarks of this time period. As the name implies, children at this age have difficulty with abstract and hypothetical thinking but are learning how to logically think about concrete things. Children implement inductive reasoning, generalizing from the specific (an example would be dad drives a red car, therefore all dads drive red cars). Deductive reasoning remains a challenge, requiring the child to understand something specific based on a generalized rule. Two other important cognitive skills emerge during this stage: *conservation and reversibility.* Children who have mastered conservation now realize that, as in the example above, there is the same amount of water in both glasses regardless of height. In addition, children in this age group develop the capacity to see things from someone else’s point of view, marking the end of egocentrism. This contrasts somewhat with theory of mind research. *Theory of mind* is the ability to recognize someone else as another entity with their own thoughts and feelings and emerges between ages 4 and 5. Learning *that* someone else thinks differently than oneself is one thing, anticipating *what* that person may be thinking or feeling is more complex and develops later.

This ability and others further develop in Piaget’s final stage *formal operations* from age 12 and older. Here, deductive reasoning develops, with many math and science implications. The ability to think abstractly appears, allowing for better planning and organization and problem solving. Trial and error is no longer necessary to come to a conclusion, results can be anticipated. Though cognitive milestones have been discussed in the context of Piagetian stages, it is worth noting other developmental theories which help predict how and why children acquire the aforementioned skills. *Information processing theory* holds that children are goal-directed problem solvers who work to achieve certain ends. Improvements in memory, processing speed, planning, and logic help facilitate learning and solving which leads to more efficient approaches and greater knowledge. Change occurs continuously, gradually, and more subtly than in a stage-based paradigm as Piaget proposed. Similarly, *Lev Vygotsky* postulated that children continuously grow as social creatures heavily influenced by their social and cultural environments. The *dynamic systems theories* attempt to incorporate many factors viewing children as constantly evolving products of their past and present adapting to the context of their physical abilities and social environment.

Sleep wields tremendous influence on cognitive and physical development and has its own unique process. At birth, infants sleep 16 to 18 hours per day, including nighttime sleep and their two or more daytime naps. By age 1, there is typically just one nap, and daily totals are down to 15 hours. This is further reduced to 13 to 14 hours by age 2 and 12 hours by age 4, with naps typically ceasing. Common adult patterns of 7 to 10 hours are seen by ages 10 to 14. On polysomnography, rapid eye movement (REM) sleep dominates the first year. By ages 3 to 4, deep non–rapid eye movement (NREM) sleep achieves a more adult-like share. It is worth noting that sleep can be highly individualized and influenced by culture. The importance of sleep cannot be overstated, with impacts on memory, learning, and physical growth. Recent evidence has shed light on the glymphatic system, which eliminates neurotoxic waste (proteins including beta-amyloid and metabolites) from the CNS during sleep. Finally, some sleep phenomena which in and of themselves are not pathologic, including nightmares, are often reported, typically at age 5. Sleep terrors (also called night terrors) and sleepwalking occur in

NREM stage 3 and are not uncommon in healthy children. Other normal sleep phenomena include hallucinations while falling asleep (hypnagogic hallucinations) and on waking (hypnopompic).

SOCIAL DEVELOPMENT

Social maturation is traditionally divided into four phases beginning with the attachment period and ending with late adolescence. There are many theories that attempt to explain social development (see Table 34.2–1).

Attachment theories explain the development of the sense of self. “Attachment is a deep and enduring emotional bond that connects one person to another across time and space” (Ainsworth, 1973; Bowlby, 1969). Infants have their primary needs met by a caretaker, typically a parent, and the emotional bond that forms between them becomes the foundation for the child’s social, emotional, and cognitive development. This *affective bond* provides the context for the “emerging pattern of dyadic regulation of emotion” (Stroufe, 2000).

The infant’s behavior directed toward the caregiver becomes organized based on needs; thus, the quality of this attachment impacts their survival both biologically and psychologically. A healthy attachment supports the infant’s exploration and mastery of the world. There are phases in the development of attachment that begin with *preattachment* at ages 0 to 6 weeks. From 6 weeks to 8 months, attachment progresses based on the responsiveness of the caretaker, and from 8 months to 2 years, *reciprocal* relationships begin and the child organizes around their acquisition of mobility and the “secure base experience.”

The historical leaders in attachment theory include John Bowlby, Harry Harlow, Rene Spitz, Mary Ainsworth, and Mary Main. Disorders of attachment are included in the *Diagnostic and Statistical Manual for Mental Disorders,* fifth edition (DSM-5), and its text revision (DSM-5-TR) and their criteria will be reviewed in the chapter on abnormal child development.

Bowlby developed his theory by borrowing from evolutionary thinking and derived from the idea that the attachment of mother and infant was “due to a species-typical behavioral pattern to promote infant survival.” He also incorporated ideas from Piagetian cognitive theory and the concept that “with increasing schema comes increasing complexity of thought” and applied them to the intensifying connection of the infant’s attachment behaviors.

Two researchers in the 1940s and 1950s provided the seeds for the idea that an infant has more than basic physical needs. Psychologically, the infant needs and craves human contact. This was demonstrated in the Harlow studies of rhesus monkeys’ preference for cloth monkeys and in Spitz’s *hospitalism* research which confirmed a failure to thrive in infants who had their biologic needs met but did not have a primary attachment figure with whom they had physical contact.

Spitz described the concept of *anaclitic depression*, where separation from the caregiver leads to depression, withdrawal, and loss of milestones.

Ainsworth’s *Strange Situation Experiment* identified four types of infant attachment:

Avoidant—needs frequently not being met by the caretaker
Securely Attached—needs were generally met by the caretaker
Ambivalent—needs inconsistently met
Disorganized–Disoriented—correlated with a history of maltreatment

Margaret Mahler’s more complex theory proposes a sequence of attachment which, if successful, enables an individual to establish a secure sense of self. An infant who is securely attached and has established *basic trust* also experiences appropriate separation anxiety when away from the primary attachment figure.

Mary Main has developed an attachment interview for adults to assess the quality of their childhood attachments. She also described a new attachment classification to apply to Ainsworth’s Strange Situation test, the disorganized/disoriented attachment classification.

Advances in biotechnology support the possibility that attachment begins in utero. Thomas Verny, MD, in his book *The Secret Life of the Unborn Child* (1981), began the discussion of this and the idea of the “attachment pregnancy,” and guides for parents to foster healthy in utero attachments have been popular recently.

The changing dynamics of gender roles for parents as well as the changing identity of the nuclear family have led to new research which has generally supported the concept that there are no great differences in quality of attachments in lesbian, homosexual, or transgender families with their children.

Successful secure attachments in infancy correspond to later psychosocial functioning and are characterized by better peer relationships, more cooperation with parents and teachers, and greater security in unfamiliar social situations and in the exploration of new environments. A child’s sense of self is generally more secure with positive early attachments, which are the foundation of emotional development. There are many consequences of abnormal attachments that will be discussed in the sections on psychopathology including feeding problems, disruptive behavior disorders, and impaired ability to sustain lasting relationships.

Morality

There are societal and cultural norms that guide one’s behaviors and actions. The internalization of these standards is a process that begins at birth when infants become aware that their behavior elicits a corresponding behavior in their caretaker, such as when a parent hugs a smiling happy infant. This cause-and-effect relationship is observed by infants and young children and becomes the basis for the rules that developing children assimilate and accommodate into their moral foundation. Children feel sadness and shame when they are punished or see that their behaviors bring displeasure to their parents or other important adult figures. Therefore, behavior is shaped by the fear of punishment, and life can be explained and organized within the framework of cultural rules and a sense of fair play. Children tend to go from the fear of punishment to the desire to confess. As children enter adolescence and reach puberty, they develop guilt and the ability to be critical of their own behaviors and transgressions. In many cultures, this is the age when children's lives become their responsibility and their conscience must be their guide.

There are many different theories of moral development but the most famous is that of *Lawrence Kohlberg,* which built on the foundations of Piaget's theory of cognitive development. Kohlberg's work was criticized for being too culturally biased toward the middle-class male and, despite revisions over the decades, is still controversial. *Carol Gilligan* in 1982 offered an alternative theory, which corresponds to morality growing in parallel to empathy. Her theory had a gender basis, with males' moral development developing into a system dominated by "the ethics of justice and the assertion of rights" whereas "woman's ends in compassion and an ethic of caring."

EMOTIONAL DEVELOPMENT

The ability to acquire and express emotions and feelings is essential to adult functioning. Learning to identify, understand, express, communicate, and modulate affect is key to successful relationships. An infant's task is to learn to be emotionally responsive and not react to internal feelings and anxiety. This is achieved through the maturation and the development of coping skills. There are many theorists who have attempted to describe emotional maturation, with achievements highlighted in Table 34.2–1.

More recently, theories integrating the neurobiology of brain maturation with social interaction have focused on the interaction between genetics, environment, and behavioral patterns to explain emotional development and maturation.

All of the theories to describe emotional maturation can basically be divided into four stages with basic milestones. Stage I is the acquisition of basic emotions that are learned through the interaction of the infant with others, including the use of mimicry. Mirror neurons, which are neurons that fire when one acts or observes an action, are proposed as being an essential pathway for this acquisition of a repertory of emotions by the infant. Stage II involves the development of self-conscious emotions, which are derived from approval or disapproval experienced and include shame, envy, embarrassment, pride, and guilt. The ability of emotional self-regulation is the task of stage III, which continues into middle childhood. Stage IV is marked by true empathy, the ability to understand and share the feelings of another.

Temperament

Temperament has fascinated scientists since ancient times when Galen of Pergamum made his prophecy “that much of human behavior can be predicted according to an individual’s temperament.”

Stella Chess and Alexander Thomas made important contributions to the study of temperament in the 1970s. They defined three major clusters which are dependent on the perceived sense of ease with which children interact with their environment. The three different styles were assessed through the categorization of nine types of behavior that they defined as dimensions of temperament, including activity level, regularity/rhythmicity, approach or withdrawal, adaptability, threshold of responsiveness, intensity of reaction, quality of mood, distractibility, and attention span and persistence. Their longitudinal study sample showed the following distribution which was generalized to apply to the general population:

One in 10 children had a *difficult* temperament.
One in six was categorized as *slow to warm up.*
Four in 10 were characterized as having an *easy temperament.*

The *goodness of fit* between parent and child as described in their book, is an important factor in working with parent–child relational problems therapeutically. Jerome Kagan, inspired by Galen, also did work on temperament and described two main types of temperament: inhibited and uninhibited. He stated that “temperament refers to stable behavioral and emotional reactions that appear early and are influenced in part by genetic constitution.” Behavioral geneticists are now exploring specific genetic polymorphisms that contribute to temperament. Some research cites polymorphisms in serotonin transporter and promoter region genes as having an effect on personality development. In addition, polymorphisms in the dopamine, serotonin, and norepinephrine transporter genes affect temperament.

MOTOR DEVELOPMENT

Perhaps more than any other developmental domain, gross and fine motor development is highly intertwined with progress in other areas. Motor development begins in utero, and is experienced by a pregnant mother as kicking. At birth, a premature CNS renders infants with little control over their actions. At this stage, reflexes are prominent, such as the grasping, rooting, sucking, swallowing, startle, and Moro. These reflect CNS functioning and disappear at predictable time periods.

Cortical columns are being laid down during the first 6 to 7 months of life and synapses are exploding in number, allowing for greater complexity and control of actions. At 2 to 4 months of age, infants can support their own head and make smoother movements in their extremities, demonstrated by shaking their toys. Some infants may be able to roll over from their stomach to back, and by 6 months, they can roll over in both directions. Also at 6 to 7 months, they can sit without support and may start to rock back and forth as if they are trying to crawl, which they will be doing over the next 2 to 4 months. A developing sensory system involving all modalities but particularly hearing, proprioception, and vision facilitate the emergence of new skills, and will continue to help them hone. Hand-to-hand transfer occurs at 7 to 8 months, first grossly then more finely, aided by a *pincer grasp.* This is when something is held between the thumb and index finger, first seen at about 9 months, and with practice develops strongly over the next year.

Clinical Correlate

Infants are unable to roll over from their stomachs to backs before 6 months, a primary reason the American Academy of Pediatrics has recommended babies be placed to sleep on their backs in order to reduce the chance of sudden infant death syndrome (SIDS).

A 9- to 10-month-old infant can stand with support and may start walking while holding onto furniture, a practice called *cruising.* Walking is typically reported at 12 months, with a normal range of 9 to 15 months. Highlighting the interdependent nature of development, the newfound ability to walk corresponds with Margaret Mahler's separation–individuation subphases of practicing and rapprochement.

By 18 months, toddlers can drink from a cup, eat with a spoon, and help dress themselves. Athletic abilities emerge at age 2, with running, kicking, throwing, jumping, climbing, and copying straight lines. Simultaneous cognitive development is crucial as these skills require a coordinated effort involving attention and planning. A 3 year old's athletic skills become more refined, and the child can climb stairs and show off the skill of riding a tricycle. By the age of 4, movements continue to improve, with catching skills and hopping abilities. Visuomotor coordination is needed and spurs development through activities such as sports and art, the latter aided by an ability to hold a pencil appropriately. These actions strengthen synapses in the developing cerebellum, which is fully myelinated by age 4, and in turn facilitates further coordination. This level of dexterity allows pouring and simple food-cutting behavior to occur, which is much improved by age 5. At this time, the child can engage in basic gymnastics, such as somersaults, and can hop and begin to skip. Hand preference is typically established by age 5. The ability to tie shoelaces generally appears within the next year or 2.

Toilet training is influenced by culture, but myelination of pyramidal tracts allows for sphincter control by 18 months, and children can start toilet training as early as age 2. They typically develop bowel control before the bladder, and the vast majority of Western children are toilet trained by ages 3 to 4. Nighttime bladder control is typically achieved months to years later between ages 5 and 7.

As with all development, it is imperative to keep in mind that the listed ages should be considered normal ranges. There is a high degree of variability, and the amount of delay, as well as pervasiveness of delays, should inform clinical suspicion of abnormality. Typically a 3- to 5-month delay in the early milestones (sitting without support, standing, holding on, first steps) is granted before there is a concern, and a larger 10- to 15-month window for later complex achievements (such as climbing stairs, jumping). Family history is important, as gross motor development is considered to be highly influenced by genes. Environment and stimulation are, of course, important too, particularly in fine motor development, such as utensils or pencil use, and in sharpening gross motor sporting skills. Inquiring whether a skill has been lost or never developed is also a crucial piece of clinical history.

SENSORY DEVELOPMENT

Imagine walking on a crowded city street at rush hour: neon lights flashing, sirens wailing, mysterious scents wafting, and fellow pedestrians obliviously making contact. In a mere instant, the body is flooded with a barrage of stimuli. That the mind can perceive, organize, and make sense of it all to the point where such a moment would be considered unremarkable is in itself quite remarkable.

Infants are born with all of their primary senses working in some capacity, some more developed than others. Within the first year, however, there is tremendous growth across the sensory modalities. As with other domains, there is a split into how important nature or nurture is in sensory development. For senses fairly functional at birth, genetics play a large but not exclusive role. For those areas that require more development after birth, any predisposition becomes dependent as well as modifiable via environmental factors.

Hearing is functional and fairly developed by birth, and in fact, there is evidence that even in the womb that infants can distinguish their mother’s voice. Despite this functionality, there is evidence that the softest sound an adult can hear would need to be amplified four times for an infant to perceive it. Children eventually reach adult levels of acuity as early as age 2. At birth, infants will turn their heads toward a sound in a phenomenon known as *auditory localization* and demonstrate a preference for voices. That infants can recognize music should come as no surprise, given the melodic nature of lullabies. Infants can discern consonant tones from dissonant ones and can be seen bouncing up and down to the music's beat.

Given how much humans rely on vision, it is surprising that this sense is the least developed at birth. In the early months, infants require great contrasts in color to make distinctions. Their color-sensing retinal cones are immature and inefficient at capturing light. Their visual acuity is quite poor, with vision estimates ranging from 20/120 to 20/800 at birth. There is an explosion of improvements made as the cells that will make up the visual cortex proliferate, reach their destination, and then make and break connections. During the first 6 months, 18,000 new visual synapses have the potential to form. Infants have near-adult levels of visual acuity by 8 months, and by age 6, their vision is full.

A number of visual experiences appear to be present at birth. Research has shown that infants possess *perceptual constancy,* where an object is known to be a constant size or shape. Infants also possess the depth cue known as *optic expansion,* where an object getting closer is perceived to be approaching. They can also differentiate human faces. Eye tracking begins at 2 months, and infants are drawn to moving stimuli. Along with this newfound skill comes the ability to take in more of an object and process it. This phenomenon is particularly noteworthy when it comes to looking at faces, as 2 month olds will scan a face much more comprehensively and will spend significantly more time looking at eyes and mouths. This has implications for social, emotional, and language development.

At 3 to 4 months, depth perception is improved via *stereopsis,* where the quickly maturing visual cortex uses the slightly different images perceived by each eye to calculate depth. At 6 to 7 months, infants can demonstrate monocular depth, perceiving depth with one eye.

Infants (much like adults) have a preference for sweets, beginning in utero. An ingenious study by de Snoo (1937) demonstrated that when saccharin was injected into the amniotic fluid, the fetus would drink more of it and excrete it via their mothers, helping to decrease high amniotic fluid volumes. Odor perception is inferred to take place in the womb as well, based on the fact that amniotic fluid has discernible scents and that this fluid comes into contact with olfactory receptors. After birth, infants show clear preferences for their mother’s scent.

Touch is inferred to begin in utero, when a fetus may be seen grasping the umbilical cord, touching other parts of its developing body, and even sucking its thumb. Learning one’s orientation in space helps develop proprioceptive skills. Initially, after birth, infants will explore new objects orally, putting everything in their mouths. They eventually develop stronger motor and visual skills and learn their environment through touch.

The human mind is able to integrate stimuli from various senses (and even multiple stimuli of just one sense) into a cohesive explanation through what is called *intermodal perception.* This ability allows one to successfully navigate the busy city street, all while listening to music.

GENDER IDENTITY

There are multiple theories of gender identity development, including biologic, cognitive, developmental, and social learning theory. There are differences between gender identity, sexual identity, and sexual orientation. Gender development begins in utero. During the first trimester, fetuses with a Y chromosome have hormonal masculinization produced by the release of androgens, and feminine hormones and development are inhibited. The fetus with only X chromosomes develops ovaries at the end of this trimester. This is essentially how infants are born, with most of the development of secondary sex characteristics beginning in latency for girls and at preadolescence for boys.

A person’s *gender identity* can be the same or different from their sexual assignment at birth.

The concept of gender identity is defined as the person’s personal experience of whether they are male or female. A person comfortable with their gender assignment at birth is termed *cisgender.* People with gender identity disparity and discomfort can be gender nonconforming or *transgender,* and some societies define a third or other gender. Societal gender standards are typically binary and impact a developing child's social identity.

Most theories and research support that core gender identity is formed by age 3. Gender dysphoria is a marked incongruence between one's experienced or expressed gender and assigned gender. Gender dysphoria can be caused by attempting to reassign a child's gender and can lead to serious consequences, including depression and severe anxiety. It is thought that, between the ages of 6 and 8, gender identity has coalesced. However, recent evidence suggests that a percentage of people may later shift identities after puberty. Due to the historical changes in Western societal attitudes toward sexuality, research is being done on gender identity development and disorders as well as parenting styles such as gender-neutral parenting that are helpful for the gender nonconforming child.

The *S.A.G.E. Test,* the Sex and Gender Explorer, is one of many new tests developed to assess gender identity.

Gender roles and gender relationships in society have changed drastically within the last century, as have sexuality and the acceptance of nonbinary sexuality; as social identities change with this new acceptance of different gender and sexual roles, so will parenting and child-rearing practices. The days of defining gender and sex roles in infant toys, clothes, and play are changing. The United States military now allows women in combat, and men are staying home to care for children. Mental health professionals need to assist in maximizing a child's development by supporting an understanding and acceptance of new forms of family, gender, and sexual identities.

RACIAL AND ETHNIC IDENTITY DEVELOPMENT

A child's development in the area of racial and ethnic identity is a process that begins early and evolves over time. Since race is a social construct that is primarily based on the child's phenotype and systematized societal hierarchies, some may wonder what place it has in childhood development. Ethnicity and culture, on the other hand, refers to the shared customs, norms, beliefs, and history that contribute to child’s sense of belonging to a community as they develop their sense of self. The development of a child’s racial and ethnic identity involves the intersection of healthy childhood social development with established social hierarchies, values, and preferences. In the social context that is characterized by the privilege of majority groups, there is often prejudice, bias, and discrimination toward minority groups. These norms are learned and internalized by children of majority and minority groups.

The developing brain is intricately involved in processing race-based information. The identification of in-group and out-group faces is a critical function played by the fusiform face area, anterior cingulate, amygdala, and anteromedial prefrontal cortex, which mediate and interpret this information. There is evidence that the developing brain already begins to categorize faces into groups. In the first year of life, it is developmentally appropriate for infants to demonstrate a preference for in-group faces and tend to maintain an in-group preference for the first 2 years of life. As the child approaches age 3, there is more explicit labeling of color groups, and children are able to draw a self-portrait reflective of their particular skin color. As toddlers, some children have already inferred social hierarchies and will demonstrate majority racial group preference if given a choice. In the United States, this is evidenced by a pro-White bias. While not pathologic, it reflects an acquired internalization of the societal hierarchy. During ages 6 to 10, children, in their effort to apply logic to the social hierarchy, may begin to create rules around why racial hierarchy exists and thus give them some rational basis (this racial group is not hardworking; therefore, they don’t have money or another racial group is better off because they work harder). Positive and negative social stereotypes are thereby reinforced in their young minds, particularly if not challenged. Also, during ages 6 to 10, explicit racialized language may be subdued as youth learn to avoid talking about race explicitly. During late childhood and adolescence, as they work to consolidate their own social identity, many of the early messages about social position, stereotypes, and hierarchies become more fixed ideologic positions. At the same time, it may be more difficult to discern implicit biases which are not endorsed and are out of awareness.

There are proactive strategies to promote healthy racial/ethnic identity development. For children from majority racial/ethnic groups, proactive discussions about human diversity, race, and ethnicity can lead to discussions about individuality, fairness, and the negative impact of bias. Developing relationships with children from diverse racial groups can diminish established social stereotypes. Avoiding majority group children's exposure to biased and prejudiced language and ideology which does not encourage critical thinking about established racial hierarchy can be impactful. For children from a majority race/ethnicity, the social context already privileges their identity. However, specifically for minority youth, efforts to imbue positive racial/ethnic identity through positive or neutral representations of the racial group in media, role modeling, and other areas of the social context can diminish stereotypes and promote a positive racial/ethnic identity. Also, efforts to promote a more equitable society overall can reduce race-based social hierarchies.

PSYCHOSEXUAL DEVELOPMENT

Sigmund Freud's contributions to psychiatry and understanding of the mind are the subjects of numerous textbooks and even institutions in and of themselves. As this chapter is dedicated to development, this section will solely focus on a portion of Freud's theory, that of psychosexual development and its contributions to character formation, from his 1905 piece *Three Essays on the Theory of Sexuality.*

Freud postulated that children go through successive stages in childhood: oral, anal, phallic, latency, and genital. Their names correspond to the erogenous zone from which Freud believed *psychic energies* attach to (or cathect) at different times of life. Psychic energies are instinctual drives that motivate the individual, and at the time, this theory proposed that drive was sexual (aggressive motives would later be emphasized as well).

Unresolved conflicts can arise at any time during any phase, leading to a variety of personality types. In the *oral phase* (from birth until about age 1), an infant's main desire, according to Freud, is to breastfeed (or bottle feeding—a warm caregiver is more important than the mode of feeding). Toward the end of the first year comes the emergence of teething and biting, aggressive tools. Undergratified suckling needs (such as neglect or emotional indifference) can lead to jealousy, envy, and a seeking and consuming nature. The typical example is the oral fixation, someone constantly chewing or smoking. A clinging dependency may also be seen and manifested by being unwilling or afraid to let go of someone or something for fear there will not be more. On the contrary, one whose needs have always been met may expect things will always work out and maintains an optimistic nature. This belief may lead to passivity and inactivity, on the other hand, and the potential for fewer coping skills when a need is not met. An infant's sexual (and aggressive) drives can be met with numerous responses by his caretaker, which can lead to a fear of losing the caretaker. To placate these fears, the baby will implement a defense such as denial of aggression, which, while adaptive in infancy, can be destructive later in life.

In the *anal stage* (ages 1 to 3), the psychic energy has shifted, and control becomes a central theme: control over one's autonomy, control over one's impulses, control over one's body, and sphincters. Parental demands increase, and compliance and rebellion with these requests are at odds here, contributing to the "terrible twos." Whereas the oral stage is a symbiotic one between the caregiver and the infant, the newly developed abilities to walk and talk make the anal stage marked by separateness, or the *dyad.* Frustration and aggression abound as the toddler struggles to meet expectations and master control. Tolerating ambivalence toward others, learning to titrate aggression, and accepting that caregivers will not leave or withhold their love is crucial for a successful resolution. It is in this stage where the anal-compulsive character originates, with the Freudian hallmark triad of pedantry, parsimony, and miserliness. A love of order and cleanliness embodies this person, who translates into the obsessive-compulsive personality type. The opposite is one who lives in disordered chaos.

The phallic phase (ages 3 to 6) is marked by the child's sexual desires for their opposite-sex parent. An obstacle to this achievement is the same-sex parent, who elicits murderous wishes from the child. In boys, this is known as the *Oedipus complex,* and in girls, *Electra.* These forbidden thoughts evoke fears of bodily injury, notably castration anxiety in boys. Fear of injury is indeed typically seen during this time. These fears, as well as impractical realities, eventually force the child to give up his quest and alternatively identify with the same-sex parent. In doing so, he internalizes his parents' rules and mores, ending the phallic phase with the formation of a superego. There are now three entities involved (child plus mom and dad), and conflicts in this phase lead to issues in triadic relationships. Unresolved conflicts in this stage may lead to myriad traits, from self-evident Oedipal ones to difficulties with following rules.

Latency follows from the resolution of the Oedipal complex until puberty. Freud believed this time was one of relative calmness sexually, though not entirely static. Psychic energy is invested in academic and social avenues as the child goes through grade school. This phase is dominated by school and peers, learning socialization, and rules. Values and ideals are solidified as the newly formed superego evolves from an external presence to an internalized one.

Though outside the scope of child development, following latency, Freud described the genital phase, where the genitals (as in the phallic stage) again become the source of libidinal energy, but now the pubertal adolescent has biologic potency. This newfound ability confers its own set of conflicts, and the teenager moves from within the family to outside the family.

It is important to bear in mind that these character types are simplifications. In addition, this theory is psychological and does not account for innate tendencies, which were indeed noted by analysts as well. Finally, when conflicts occur, they are from repeated behavior patterns between a child and the important caretakers. Though many are skeptical about the veracity of Freud's theories, his contributions are irrefutable. The impact of early experiences remains crucial to understanding an individual, as does the relationship with family members. The significance of an unconscious—that feelings occur outside of one's awareness—has an enormous bearing on how one conceptualizes the mind and treats patients clinically.

CONCLUSION

In summary, development is the acquisition of new skills or abilities and the various responses both intra- and interpersonally. Humans are born with a genetic background, and the environment contributes to which pathways get further strengthened or pruned. Changes in the brain allow for new possibilities in the developing child. Small advances begin to accumulate, and more possibilities arise. By the end of childhood, a person who started as mostly innate reflexes has become capable of writing essays about the future, performing complex athletic activities, establishing a sense of identity, and engaging in deep reciprocal relationships. However, although this section has focused on child development and all the significant achievements that are made during that period, it is important to note that development continues throughout the lifespan.

34.3 Adolescent Development

Ardis C. Martin, M.D., and Caroly Sue Pataki, M.D.

Adolescence is a critical period of neurobiologic and physical maturation leading to increased psychological awareness and more sophisticated social, cognitive, and emotional engagement with peers and adults. Striking features of social and emotional growth in adolescence include (1) increased affiliation with a peer group, (2) striving for more autonomy from parents, (3) increasing ability to “mentalize,” that is, understand what others are thinking and feeling, (4) an increase in risk-taking behaviors, and (5) greater sensation seeking. A convergence of data from neuroimaging studies, including the work of Blackmore and Mills (2014) have been able to identify certain regions of the adolescent brain specialized to produce increased mentalizing, and other regions of the brain that remain immature, but are adaptive to changing environmental demands through their “plasticity.” The varying levels of maturation in diverse regions of the adolescent brain lead to a seeming paradox, for example, between an adolescent’s increased ability for empathic social thought process and at the same time reckless risk-taking behaviors. This apparent “mismatch,” that is, varying degrees of maturity across different regions of the adolescent brain has been referred to by some researchers as the “Dual System Model.” The work of Strang, Chein, and Steinberg (2013) supports a view that increased risk-taking in midadolescence may be, in part, due to an increased reactivity of the social and emotional regions of the brain in the context of less mature cognitive control brain development. The social and emotional reactivity system is believed to be localized mainly in the ventral striatum and ventromedial prefrontal cortex (PFF), whereas the cognitive control system is believed to be localized in the lateral prefrontal, parietal, and anterior cingulate cortices. Emerging evidence from neuroimaging studies supports a correlation between increased adolescent social awareness and mentalizing abilities and activity in three specific brain regions including the medial prefrontal cortex (mPFC), the posterior superior temporal sulcus (pSTS), and the temporoparietal junction (TPJ). However, as older adolescents transition into young adulthood, there is a decrease during mentalizing tasks in the activation of the mPFC. Thus it appears that during the development of mentalizing abilities, the mPFC is a critical brain region, however, once the process is developed, in adulthood, this region no longer predominates, and other brain regions may take over this function. Giedd (2014), and other colleagues, using neuroimaging to track adolescent brain development find that gray matter in the brain, such as the PFC, does not grow larger after puberty, on the contrary, it matures by becoming more specialized, that is, by a process termed “pruning,” which ultimately leads to a diminished size. Gray matter is at its peak volume in girls at approximately age 11 years, and in boys, at approximately 13 years. On the other hand, white matter, representing myelinated brain regions continues to increase throughout childhood and adolescence. The continued increase in white matter reflects increasing "connectivity" and continued ability of the brain to adapt to new cognitive demands throughout adolescence. Thus, the increasing and less specialized white matter growth allows for greater cognitive adaptive brain function, with a resulting delay in its maturation in adolescents. Consequently, adolescents experience a longer period to learn and respond to novel cognitive information and develop new responses, however, this delays the brain maturation guiding cognitive control and decision making.

DEFINITION

Adolescence is the period of maturation between childhood and adulthood heralded by the physiologic signs and surging hormones of puberty. It is a time when peer relationships deepen, autonomy grows, and intellectual pursuits intensify and a sense of social belonging is sought. Adolescence is a time of accelerated social and psychosexual exploration, culminating in an integrated concept of "self." Adolescents can be viewed as neurobiologic "works in progress," often consumed by academic, interpersonal, and emotional challenges, and exploring new territories using their talents, and experimenting with social identities.

WHAT IS TYPICAL IN ADOLESCENCE?

The conceptualization of adolescence as a continual struggle, with its defining feature of intense psychic pain and severe turmoil, was a historical notion. The hypothesis that most adolescents experience enduring severe psychological distress, intense depressive symptoms, severe mood lability, and a disruption of their usual conduct was not borne out by epidemiologic studies. Although certain psychiatric disorders, such as major depression, schizophrenia, and bipolar disorders, emerge with greater frequency in adolescents than in younger children, the majority of adolescents are free of psychiatric disorders. For up to approximately 75% of youth, adolescence is a period of successful adaptation to physical, cognitive, and emotional changes, largely continuous with their previous functioning. Thus, the majority of adolescents display reasonable autonomy in decision making, increasing independence in completing academic work, and successful peer relationships without significant alienation from their families or the emergence of conduct-disordered behaviors. Psychological maladjustment, self-loathing, disturbance of conduct, substance abuse, affective disorders, and other impairing psychiatric disorders emerge in approximately 20% of the adolescent population. Adolescent adjustment is, in general, continuous with previous psychological function; thus, psychologically disturbed children are at greater risk for psychiatric disorders during adolescence. Adolescents with psychiatric disorders are at increased risk for greater conflicts with families and for feeling alienated from their families. Although up to 60% of adolescents endorse occasional distress or a psychiatric symptom, this group of adolescents functions well-academically and with peers and describes themselves as generally satisfied with their lives. Studies conducted since the 1980s indicate that most adolescents endorse more acceptance than rejection of their parents' values and lifestyles, and few report feelings of isolation or alienation from their families.

The developmentalist Erik Erikson characterized the normative task of adolescence as identity versus role confusion. In other words, adolescents, faced with the task of applying childhood talents, strengths, and experiences to their evolving physical and emotional selves, must be able successfully to change “who they are” so as to build a more mature identity. The integration of past experiences with current changes takes place in what Erikson termed ego identity. Adolescents express various aspects of their psychological selves by becoming fans of heroes or other well-known musical or political idols. Some adolescents appear consumed by their identification with a particular idol, whereas others are more moderate in their expression. Adolescents who feel accepted by a peer group are less likely to become consumed by adoration of an idol. Adolescents who are socially isolated, feel socially rejected, and become overly identified with an idol to the exclusion of all other activities are at higher risk for serious emotional problems and require psychiatric evaluation.

Adolescence is a time to search for ideals and social values that can be carried into adulthood. Erickson used the term moratorium to describe the interim period between the concrete thinking of childhood and a more evolved complex abstract thinking and ethical development. He defined identity crisis as a normative task of adolescence in which adolescents pursue alternative behaviors and styles and then successfully mold these different experiences into a solid identity. A failure to do so results in identity diffusion, or role confusion, in which there is a lack of cohesive or confident sense of identity. Successful development creates the primary psychological virtue of fidelity, characterized by the ability to relate to others and form genuine relationships—setting the stage for the next developmental phase, intimacy versus isolation. Adolescence is the time to bond with peers, experiment with new beliefs and styles, fall in love for the first time, figure out who one wants to be and where one fits in, and explore creative ideas for future plans. The literature leads to the conclusion that the majority of adolescents go through this developmental process with basic optimism and good self-esteem, maintain good peer relationships, and sustain basically harmonious relationships with their families.

CULTURAL CONSIDERATIONS

Racial and Ethnic Identity Development During Adolescence

According to the 2018 to 2019 U.S. Census Bureau report, teenagers age 10 to 19 make up 13% of the U.S. population and are rich in ethnic and racial diversity. Of that 13%, 50% are white, 25% are Latinx, 14% are Black, 5% are Asian, 4.5% are multiracial, 1% are American Indian or Alaska Native, and 0.5% are Native Hawaiian or Pacific Islander. First- and second-generation immigrants make up 26% of all children ages 0 to 17 years.

Erickson posited that the goal of adolescence is the formation of a solid and positive sense of self. He believed the process of self-exploration could prove challenging for adolescents whose cultural identity is not supported by their own culture nor validated by their community and foresaw the potential problems faced by youth from diverse racial and ethnic backgrounds.

When looking at adolescents' identity development, providers would be remiss if they don't look at the role of ethnic and racial identity development. Ethnic and racial identity is a crucial part of adolescents' discovery of their sense of self-worth and self-image–how others see them, how they see themselves, and for teens of color, how their race becomes a salient component of their lives. Researchers have found that ethnic and racial attitudes start to emerge around ten years of age, and examining one's racial and ethnic identity begins in middle school and junior high. Racial and ethnic identity is essential to all youth, but especially for teens of color. In addition to the tasks of separating and individuating from their families, establishing a sense of autonomy, coming to terms with their sexuality/gender, identifying their own religious and political views, adolescents of color must also develop their identity as it corresponds to their racial and ethnic identity. They are trying to navigate where they belong, identify within a particular race or ethnicity, share values, and develop a sense of self.

William Cross's racial identity development model has been a robust framework for understanding the process that teens of color, particularly African Americans, go through when developing their racial identity. The model includes the following phases: pre-encounter, encounter, immersion–emersion, and internalization. Adolescents in the pre-encounter stage may consciously or unconsciously devalue or have little to no awareness of their race and how it impacts their life, concurrently valuing the majority culture's ways and values. In the encounter stage, the adolescent experiences an event, positive or negative, that makes them evaluate themselves from a racial perspective; for teens of color, this is typically caused by their first-time encounter with discrimination or racism, which challenges their worldview and sense of belonging. In the immersion/emersion stage, teens of color begin to explore their racial identity, engage more within their respective cultures, and develop a sense of pride. In the internalization phase, adolescents can incorporate into their self-concept, a sense of self-confidence and secure identity.

Several other models were created to examine the racial and ethnic identity development of people of color, immigrants, and their majority counterparts. Janet Helms looks at white identity development, W.S. Carlos Poston looks at biracial identity development, and John Berry looks at ethnic/immigrant identity development. Jean Phinney examined the various models and, finding commonalities across them developed her three-stage model to describe racial and ethnic identity development: Unexamined Ethnic Identity, Ethnic Identity Search (Moratorium), and Achieved Ethnic Identity. In the unexamined stage, teens of color do not associate much personal meaning with their race or ethnicity and prefer the majority culture. The ethnic identity search stage is often triggered by an experience of discrimination forcing the adolescent to become aware of their racial and ethnic identity. This negative experience leads them to immerse themselves in their own culture more intensely–reading, attending cultural events, grouping with others of their background, and sometimes rejecting the dominant group. In the final stage, achieving identity, adolescents can internalize their race and ethnicity, seeing the differences between their group and the majority group and the racism and prejudice that exist for their group. These stages aren’t necessarily linear and can occur at any time during early or late adolescence.

As seen across these models, the role of racism and discrimination complicates the exploration of a teen’s racial and ethnic identity development. Adolescent youth of color are forced to see themselves in terms of race because society does. Racism and bigotry create a significant amount of stress for youth of color and can hinder their ability to develop a positive self-identity and harm their mental health. It is important for adolescents of color to have access to culturally positive information, positive family interactions, and supportive relationships that convey positive regard for their racial and ethnic identity creating resilience. These experiences must be considered as they undertake the normative tasks of adolescent development. Not all teens of color will go through the process of exploring their racial and ethnic identity, but it must be considered to ensure that they have a healthy transition to adulthood.

STAGES OF ADOLESCENCE

Early Adolescence

Early adolescence, from 12 to 14 years of age, is the period in which the most striking changes are noticed—physically, attitudinally, and behaviorally; encompassing the biologic changes of puberty as well as psychological and sexual awakenings. Growth spurts often begin in these years for boys, whereas girls may have had rapid growth for 1 to 2 years prior. At this stage, many adolescents express a sense of identification with a particular peer group, often a same-sex group of peers join together, and may identify belonging to a peer group with markers including clothing, hair styles, or affiliation with certain activities. Both boys and girls begin to identify themselves as distinct members of their families, often critique usual family habits, insist on spending time with peers with less supervision, and may question previously accepted family values.

In the early stage of adolescence, there may be some degree of withdrawal from family activities, increased interest in spending time with peers, greater awareness of style and appearance, a stated goal of becoming more independent, and claims of needing less parental involvement. A new awareness of sexuality may be displayed by increased modesty and embarrassment with their physical development or may exhibit itself in an increased interest in the opposite sex.

Early adolescents engage in subtle or overt displays of their growing desire for autonomy, sometimes with challenging behaviors toward authority figures, including teachers and school administrators, and exhibit disdain for rules. At this age, some adolescents begin to experiment with cigarettes, alcohol, and marijuana. The Youth Risk Behavior Surveillance System (YRBSS) surveyed all public and private schools from grades 9 to 12 throughout the United States (more information is available at https://www.cdc.gov/healthyyouth/data/yrbs/index.htm). The 2019 report indicated that 18.1% of ninth graders had tried smoking cigarettes, 8.8% tried their first cigarette before age 13, and 0.8% of male ninth graders and 0.3% of female ninth graders had smoked at least one cigarette every day consecutively for 1 month. The report also showed that 40.2% of ninth graders have used electronic vapor products (e.g. vapes, vape pens, e-cigarettes, hookah pens, e-cigars); 40.7% of ninth-grade females, and 39.8% of ninth-grade males had vaped at least 1 day during the month prior to the survey; 3.1% of ninth-grade females, and 4.0% of ninth-grade males vaped daily during the month prior to the survey. The YRBSS reported that 21.9% of ninth-grade girls and 16.3% of ninth-grade boys consumed at least one alcoholic drink in the month preceding the survey, 18.7% had their first drink of alcohol before age 13, and 7.3% of ninth-graders were binge drinking–8.2% of females and 6.4% of males. The 2019 National Survey of Drug Use and Health (NSDUH) showed that 1.3% of adolescents males and 2.1% of adolescent females age 12 to 17 had an alcohol use disorder. Findings also showed a decline in underage drinking from 2002 to 2019–prevalence in the past 30 days of alcohol use decreased 41.1% for 16- to 17-year-olds, 54.7% for 14- to 15-year-olds, and 61.9% for 12- to 13-year-olds. The YRBSS reported that 22.6% of ninth-grade girls and 26.0% of ninth-grade boys have used marijuana at least once, and current use of marijuana was present among 14.6% of ninth graders. Overall, the prevalence of one or more time use of marijuana and daily current use has decreased over the last 8 years among 9th to 12th graders. With regard to other illicit drug use (cocaine, heroin, hallucinogens, ecstasy, and amphetamines) among 9th to 12th grades, the prevalence of all has decreased between 2011 and 2019. Of note, use of electronic vaping devices among adolescents has increased substantially between 2015 and 2019. According to the National Youth Tobacco Survey (NYTS), current electronic vapor product use among high school students increased 78% (11.7% to 20.8%) from 2017 to 2018.

During early adolescence, there is significant variation in the timing of acquiring new behaviors. For example, some 12-year-olds identify with popular music or wearing “adolescent” clothing, whereas other adolescents are seeking to reinvent themselves with a more mature appearing image. Epidemiologic surveys have not provided evidence for this notion that adolescence is characterized by overwhelming alienation, profound angst, and significant disruption of family relationships. In this age group, most adolescents spend at least twice as much time with their families as with their peers.

Suzanne, a 14-year-old freshman in high school concerned about being compared to her older sister, who was known as a troublemaker. Suzanne felt that her teachers didn’t value her for being her “own” person and automatically assumed that she was a poor student, always looking for a way to avoid schoolwork. Suzanne secretly smoked cigarettes, occasionally drank alcohol, and had tried smoking marijuana, however, she found it extremely annoying that her parents were always checking up on her. She rationalized that her parents’ intrusion was just because her older sister had been suspended several times for going to school intoxicated. Suzanne spent most of her time out of school in her room with her door closed, doing homework while watching TV, instant messaging her friends on her computer, and text messaging, snap chatting, and using Instagram with her friends. Although Suzanne had enough friends, and enjoyed singing in the school choir, she found herself feeling anxious much of the time and fearing that she had forgotten to finish all of her homework or studied enough for a test. She found going to class more and more unpleasant, and decided that classes were a waste of time. Suzanne began to find the school rules increasingly irritating, especially being “locked” out of the classroom if she was a few minutes late. Suzanne felt that the teachers were too strict, and never gave her the benefit of the doubt. To avoid getting into trouble for being late, Suzanne began to cut classes then she began to cut the whole day of school if she thought she was late in the morning. Before long, she had fallen behind in her work but was too embarrassed to tell her parents. She told her friends, and they helped her get some of the schoolwork, but she had missed so much work that it was difficult to catch up. Since it was getting close to her first progress report and Suzanne could not talk to her parents, she finally went to her school counselor to say that she was not going to many classes because it was too stressful to get there on time and that she was in danger of failing. The school counselor convinced Suzanne to tell her parents about her academic problems, and, begrudgingly, she agreed to a meeting with the counselor and her parents. Suzanne's parents were shocked to find out that she was so stressed, and near failing, since she consistently said that everything was fine as long as everyone left her alone. After the meeting, Suzanne realized that instead of trying to be so independent she was actually being self-destructive. Suzanne agreed to accept her parents' help with a ride to school in the morning, and despite some initial resistance tutoring sessions were started. Suzanne worked hard with her tutor, improved her grades, and began to leave her bedroom door open more often at home. She also turned to her parents and sisters for help if she did not understand something and found that they were actually helpful. Suzanne ended up with three A's and one B for the first grading period and was proud of herself. Suzanne felt less stressed and more confident after the first grading period, she was more connected to her family, and looked forward to spending more time with friends for the remainder of her freshman year.

Middle Adolescence

During the middle phase of adolescence (roughly between the ages of 14 and 16 years), peer groups begin to shift to coed, and become more predominant in their importance. Concrete signs of greater autonomy are beginning to emerge, such as learning to drive, and in some states, obtaining a driver's license by the age of 16 years. Along with a greater lifestyle of autonomy adolescents are also presented with increased responsibilities, especially in the area of social judgment. Conflict may arise when empathy and social awareness are paired with poor impulse control and decision making, potentially leading to health risks, car accidents, and alcohol and drug use. Sexual behavior intensifies in this phase of development, initiating romantic relationships is more complicated, and self-esteem becomes a pivotal influence on positive and negative risk-taking behaviors.

The 2019 YRBSS reported more frequent use of electronic vapor products among white students (14%) and Hispanic/Latinx students

(7.5%) than among Black and Asian students (5.0% and 5.1%, respectively). Overall, frequent use of cigarettes among all races of students decreased substantially since 2011 while electronic vapor product use has steadily been on the rise. Use of alcohol, that is, report of at least one alcoholic drink within 1 month of the survey time, was 26.7% for 10th graders and 32.3% for 11th graders. The prevalence of heavy drinking—five drinks or more in a row—increased with each increasing grade from 9th to 12th grade. Tenth graders reported rates of heavy drinking, 10.6%, which increased in 11th graders, 15.3%; significant decrease seen in heavy drinking across all grades since 2011. Marijuana use was found to be somewhat higher among boys than girls across all high school grades, except 10th graders, and the overall prevalence of current marijuana abuse was 28.3% among 12th graders. The prevalence of hallucinogenic drug use (LSD, mushrooms, acid) was reported to be higher in boys than girls, and lifetime hallucinogenic drug use was 8.2% among 11th graders and 9.9% among 11th-grade boys.

In this phase of development, adolescents tend to identify with a group of peers who become highly influential in their choices of activities, styles, music, idols, and role models. Adolescents' underestimation of the risks associated with a variety of recreational behaviors and their sense of "omnipotence," mixed with their drive to be autonomous, frequently cause some conflict with parental requests and expectations. These conflicts, however, for the most part, do not result in the destruction of meaningful relationships with parents or siblings. For most teens, the process of defining themselves as unique and different from their families can be achieved while they still maintain alliances with family members.

Olivia was a 16-year-old starting her junior of high school, who had just gotten her driver's license. She realized how lucky she was to have been given her older sister's old car as soon as she had turned age 16 years, but she was overwhelmed when her friends called and constantly wanted rides. Olivia drove her younger sister to school each morning, and this created tremendous friction between them since Olivia's sister always threatened to tell their parents that Olivia was an unsafe driver because she was always late and would text her friends while in the car. Olivia was a confident driver but she would become distracted when her friends were in the car talking and laughing while she was trying to concentrate on the road. Olivia felt unable to say no to giving her friends rides, even when they smoked marijuana in her car. Olivia would half-heartedly object, however, she had never been popular, and believed that she would lose the few friends she had, if she did not take risks. Olivia decided not to tell her parents about this, and so she continued to allow her friends to smoke marijuana in her car until she had a "close call" in which a police car was tailing her but did not pull him over. Olivia began to panic and had to stop his car on the side of the road. Olivia's friends congratulated her for not getting caught, however, they didn't understand how much stress this caused her. After this, Olivia told her parents that she no longer wanted to drive on the weekends, and she told her friends that her parents had taken away the car. Although Olivia was very hurt because some of her friends dropped her and began to take rides from other friends without her, she felt a great sense of relief. Olivia began to spend more time at home drawing, painting, and creating a portfolio. Olivia went through a period of social isolation and sadness, but over time, she developed new friendships with peers who took art lessons and enjoyed drawing and painting. Olivia looked forward to applying to college and was glad to be leaving the social situation in his high school. Olivia put new energy into studying and taking challenging courses in the second semester of junior year including several advanced placement classes, and found that she had more in common with classmates in these courses than her previous group of friends. Olivia felt excited and enthusiastic about entering an art program at a competitive and popular college.

Late Adolescence

Late adolescence (between the ages of 17 and 19 years) is a time when the adolescent cognitive brain processes, impulse control, and decision making begin to catch up with the social brain and behavior. During this phase, exploration of academic pursuits, musical and artistic tastes, athletic participation, and social bonds leads an older teen toward greater definition of self and a sense of belonging to certain groups or subcultures within mainstream society. As Erickson aptly described, through this exploration, an adolescent gradually moves toward a solid “identity formation.” Well-adjusted adolescents can be comfortable with current choices of activities, tastes, hobbies, and friendships yet remain open to the idea that their “identities” will continue to be refined during young adulthood. Peer interactions are primary, and some bridges may be formed with family members to increase communication and social repartee. This transition spans the completion of high school and at least the first year of college, where exploration of new relationships and interests, often in a new setting away from home, is initiated. Prior to finishing high school, however, the use of cigarettes, alcohol, and marijuana is higher than in the lower high school grades. The 2019 YRBSS reported that 7.8% of 12th graders had had the occasion to drive while they had been drinking alcohol, and 17.0% of 12th graders had been passengers with drivers who had been drinking alcohol. The prevalence of current frequent electronic vapor use was reported to be 40.4% among 12th graders. Alcohol use within 1 month of the survey was reported by 39.9% of 12th graders, 37.5% of 12th-grade boys and 42.0% of 12-grade girls, with episodic heavy drinking of more than four consecutive drinks in a row occurring in 22.4% of 12th graders. Nationwide, current marijuana use was reported by 31.1% of 12th-grade boys and 25.1% of 12th-grade girls. The prevalence of having ever used ecstasy was reported by 6.5% of 12th-grade boys and 3.4% of 12th-grade girls.

Neuroimaging studies provide evidence suggesting that during late adolescence and even into adulthood, the PFF neural networks continue to facilitate working memory, prospective memory (the ability to keep in mind an intention to do something in the near future while multitasking), perspective taking (understanding another person's point of view), and responding to others while keeping one's feelings in mind. This phase of adolescence is an exciting time for the development of finely tuned cognitive abilities, social skills, and enduring relationships.

Damien, 18 years-old, was in his second semester of college. He loved being on his own away from home and was gratified that his new college relationships seemed more real and important to him than his high school peers. Damien had no idea about what he might want to choose as a future career, and during his first semester, he had opted for random classes in many different subjects. In high school, Damien was naturally good in languages, and math without studying much. He enjoyed travel and never gave much thought to what it might be like to be settled down in a career. Damien's parents had encouraged him to explore interests during high school, however, they made it clear that since they were paying a lot of money, once he was in college, he was expected to pick a career goal as soon as possible, so that his college years wouldn't be wasted. So far, Damien had found that manty of his classmates came to college with well-defined ideas about future careers, and he began to feel pressure. Damien agonized about the infinite possibilities and wondered why many peers already seemed sure of their future goals and he felt so confused. Damien began to feel alienated by his lack of direction and developed insomnia. Damien mentioned his insomnia to his friend Emma, and she was surprised by his level of stress, and told him she viewed him as an open and social person who made friends easily and got along with everyone. Damien felt that his open and nonjudgmental style was now getting in the way of making a decision about a major where he fits best. Damien confided this to Emma, and she then challenged the rigid expectations and timeline that Damien's parents had imposed on him. Emma suggested that he take at least two more quarters of classes in any subjects that seemed interesting before feeling compelled to determine the best match for him. Damien realized that Emma's approach was more reasonable than his parents' timeline and he felt the burden of those pressures diminish. Damien had been influenced to believe that quitting or changing can be a sign of weakness. Emma's approach supported the idea that life decisions should be based on positive experiences rather than on a timeline that didn't seem to fit. After much internal deliberation, Damien embraced Emma's suggestion and decided to allow himself at least another year to decide on a major and a potential career path.

COMPONENTS OF ADOLESCENCE

Physical Development

Physical growth, along with the onset of sexual development, is identified as the "hallmark" of adolescence. Puberty is the process by which adolescents develop physical and sexual maturity, along with reproductive ability. Pubertal development begins in response to a surge of gonadotropin-releasing hormone from the hypothalamus. The hypothalamus is influenced by a multitude of physiologic and psychological factors, and the onset of puberty may be delayed or altered in situations of severe nutritional deprivation. Gonadotropin-releasing hormone acts on the pituitary gland to release the gonadotropin-luteinizing hormone and follicle-stimulating hormone. These two hormones, in turn, act to stimulate the production of a variety of androgens, testosterone, estradiol, and other peptides. Physical development during puberty is also regulated by two additional hypothalamic peptides, growth hormone–releasing hormone and somatostatin, both of which promote the release of growth hormone from the pituitary gland. Puberty unfolds over time in conjunction with the pulses and feedback loops of these gonadotropins. The first signs of the pubertal process are an increased rate of growth in both height and weight. This process begins in girls by approximately 10 years of age. By the age of 11 or 12 years, many girls noticeably tower over their male classmates, who do not experience a growth spurt, on average, until their 13th year. Even more striking are the differences in the development of secondary sexual characteristics in girls versus boys approximately 13 years old. By the age of 13 years, many girls have experienced menarche, and the majority have developed breasts and pubic hair. The initial appearance of pubic hair in both genders may occur before puberty, during adrenarche, which is dependent on hormones secreted by the adrenal glands, rather than by gonadal development. Some components of pubertal development are identical in boys and girls and include an increase in height, weight, muscle, and fat, whereas others, such as breast development or growth of facial hair, are specific to only one gender. There is wide variation in the normal range of onset and timing of pubertal development and its components. There is a set sequence, however, in the order in which pubertal development proceeds. Thus, secondary sexual characteristics in boys, such as increased length and width of the penis, for example, will occur after the release of androgens from developed enlarged testes.

Sexual maturity rating (SMR), also referred to as Tanner stages, ranges from SMR 1 (prepuberty) to SMR 5 (adult). The SMR ratings include stages of genital maturity in boys and breast development in girls, as well as pubic hair development. Pubic hair development is a less reliable measure of sexual maturity, however, because it may emerge in response to androgens from the adrenal glands before the pubertal process has actually begun. Table 34.3–1 outlines SMRs for boys and girls.

Table 34.3–1.
Sexual Maturity Rating (SMR) of Girls and Boys

SMR	Girls	Boys
Stage 1	Preadolescent, papilla elevated	Penis, testes, scrotum preadolescent
	No pubic hair	No pubic hair
Stage 2	Breast bud, small mound; areola diameter increased	Penis size same, testes, and scrotum enlarged, with scrotal skin reddened
	Sparse, long pubic hair, mainly along labia	Sparse, long pubic hair, mainly at the base of the penis
Stage 3	Breast and areola larger; no separation of contours	Penis elongated, with increased size of testes and scrotum
	Pubic hair darker and coarser, spread over the pubic area	Pubic hair darker and coarser, spread over the pubic area
Stage 4	Breast size increased	Penis increased in length and width
	Areola and papilla raised	Testes and scrotum larger
	Pubic hair coarse and thickened; covers less area than in adults, does not extend to thighs	Pubic hair coarse and thickened; covers less area than in adults, does not extend to thighs
Stage 5	Breasts resemble adult female breast; areola has	Penis, testes, scrotum appear mature Pubic hair increased in density; area

	recessed to breast contour Pubic hair increased in density, area; extends to thighs	extends to thighs

The primary female sex characteristic is ovulation, or the release of eggs from ovarian follicles approximately once every 28 days. When adolescent girls reach SMR 3 to 4, ovarian follicles are producing enough estrogen to result in menarche, the onset of menstruation. When adolescent girls reach SMR 4 to 5, an ovarian follicle matures on a monthly basis and ovulation occurs. Estrogen and progesterone promote sexual maturation, including further development of fallopian tubes and breast development.

For adolescent boys, the primary sex characteristic is the development of sperm by the testes. In boys, sperm development occurs in response to follicle-stimulating hormone acting on the seminiferous tubules within the testes. The pubertal process in boys is marked by the growth of the testes stimulated by luteinizing hormone. There is no discrete sign of the formation of viable sperm, but it must be assumed that at the time that ejaculatory capacity occurs, viable sperm are likely to be present. An adolescent boy's ability to ejaculate generally emerges within 1 year of reaching SMR 2. Secondary sexual characteristics in boys include thickening of the skin, broadening of the shoulders, and the development of facial hair.

In general, the majority of adolescents adjust well to the changes in their physical growth and maturation. Inasmuch as overall identity formation is a gradual process, adolescents incorporate their developing physical identities into their evolving adult selves.

Cognitive Maturation

Cognitive maturation in adolescence encompasses a wide range of expanded abilities that fall within the global category of "executive functions" of the brain. These include the transition from concrete thinking to more abstract thinking; an increased ability to draw logical conclusions in scientific pursuits, with peer interactions, and in social situations; and new abilities for self-observation and self-regulation. These result in an adolescent’s capacity to develop hypotheses, express altruism, create idealistic scenarios, and develop hopes and dreams for the future. Adolescents acquire increased awareness of their intellectual, artistic, and athletic gifts and talents, yet it often takes many more years into young adulthood for them to establish a practical application for these abilities.

The cognitive-developmental theorist Jean Piaget has been a central influence on the way in which clinicians and researchers understand the cognitive strategies of children throughout development and the changes that occur during adolescence. The central cognitive change that occurs gradually during adolescence is the shift from concrete thinking (concrete operational thinking, according to Piaget) to the ability to think abstractly (formal operational thinking, in Piaget’s terminology). This evolution occurs, according to Piaget, as an adaptation to stimuli that demand an adolescent to produce hypothetical responses, as well as in response to the adolescent’s expanded abilities to provide generalizations from specific situations. Recent magnetic resonance imaging (MRI) studies showing evidence of a preadolescent increase in cortical gray matter in the brain, possibly due to a wave of increased production of synapses, may be a physical correlate of the adolescent’s ability for expanded abstract reasoning. The development of abstract thinking is not a sudden epiphany but, rather, a gradual process of expanding logical deductions beyond concrete experiences and achieving the capacity for idealistic and hypothetical thinking based on everyday life. Younger adolescents may be able to verbalize an understanding of complex abstract constructs and still react to situations in rigid and concrete ways. For example, a young adolescent may be able to verbalize an understanding of the link between drug and alcohol use and health risks but cannot imagine it happening to themselves. Similarly, adolescents often believe that they can “beat the odds,” even when they understand the mathematical meaning of the probability of an event occurring. Adolescents often use an omnipotent belief system that reinforces their sense of immunity from danger, a false sense of immortality, even when confronted with logical risks. Some degree of child-like magical thinking continues to coexist with more mature abstract thinking in many adolescents. Despite the persistence of magical thinking into adolescence, adolescent cognition departs from that of younger children with regard to an increased ability for self-observation and the development of strategies to promote strengths and compensate for weaknesses. For example, an adolescent who becomes aware of a weakness in completing academic work or tests during the time allotted in school may realize that they know the material but cannot perform well in timed examinations and will make a request to the teacher to receive additional time on examinations. The ability to develop strategies for survival and use proactive methods of making them happen increases during the period of adolescence. One of the important cognitive tasks in adolescence is to identify and gravitate toward those pursuits that seem to match the adolescent's cognitive strengths in academic courses and in thinking about future aspirations. Piaget believed that cognitive adaptation in adolescence was profoundly influenced by social relationships and the dialogue between adolescents and peers, making social cognition an integral part of cognitive development in adolescence.

Socialization

Socialization in adolescence encompasses the ability to find acceptance in peer relationships and in turn the development of more mature social cognitions enabling the adolescent to accept others. It is common knowledge that, for early adolescents, the skills for developing a sense of belonging to a peer group, are of central importance to a sense of well-being. Being viewed as socially competent by peers is a critical component in building good self-esteem for most early adolescents. Peer influences are powerful and can foster positive social interactions, as well as apply a pressure in less socially accepted behaviors or even high-risk behavior. Belonging to a peer group is, in general, a sign of adaptation and a developmentally appropriate step in separating from parents and turning the focus of loyalty toward friends. Social cognition—the way in which adolescents use logic and reason in their assumptions about peers and in their peer interactions—has been explored by Robert Selman (see Asher and Gottman, 1981). After interviewing children and adolescents with respect to their interpretation of various social interactions, he identified stages of social cognition. In school-aged children and preadolescents, Selman described social cognitions as "fair-weather cooperation." That is, the friendships are characteristically on-again/off-again, depending on the level of affiliation or disagreement in the last social interaction. Thus, children between the ages of 6 and 12 years are able to engage in exchanges of ideas and opinions and acknowledge feelings of peers, but the relationships often wax and wane in a discontinuous way on the basis of altercations and good times. Friendships deepen with repeated good times, but, for some school-aged children, a variety of peers are often interchangeable—that is, a companion is sought when a given child has free time, rather than out of a desire to spend time with a specific friend. As adolescence ensues, friendships become more individualized, and personal secrets are likely shared with a friend rather than a family member. A comfort level is achieved with one or several early adolescent peers, and the group may "stick together," spending most free time together. In early adolescence, a blend of these two social modes may emerge, small "cliques" may arise, and, even within the cliques, competition, and jealousies regarding which dyads are "preferred" or higher ranked within the clique may result in some discontinuities in the relationships. In later adolescence, the peer group solidifies, leading to increased stability in the friendships and a greater mutuality in the quality of the interactions.

Moral Development

Moral reasoning among adolescents depends on the maturation of cognitive strategies for problem solving, societal conventions, exposure to familial attitudes, and personal values adopted. Morality is a set of values and beliefs about codes of behavior that conform to those shared by others in society. Adolescents, like younger children, tend to develop patterns of behaviors characteristic of their family and educational environments and by the imitation of specific peers and adults whom they admire. Moral development is not strictly tied to chronologic age but, rather, is an outgrowth from cognitive development. Piaget described moral development as a gradual process parallel to cognitive development, with expanded abilities in differentiating the best interests of society from those of individuals occurring during late adolescence. The development of trends in moral judgment has been divided into levels by Lawrence Kohlberg, who posed “moral dilemmas” to children and adolescents and subsequently characterized their responses. According to Kohlberg, morality can be divided into preconventional, conventional, and postconventional. Before adolescence, decisions regarding actions that are loosely defined as “right” and “wrong” are dependent on the anticipated consequence of those actions. School-aged children, for example, denoted as using level 1 of preconventional morality, may define actions that result in a negative consequence or punishment as “wrong” simply due to the consequence that may ensue. The most important defining feature of “right” then becomes being able to “get away with it,” and it only becomes “wrong” if there is punishment associated with it. Some young adolescents, still functioning within the category of preconventional morality but one level higher (level 2), may define “right” and “wrong” as synonymous with what is perceived as fair and reciprocal. Thus, the philosophy of “an eye for an eye, and a tooth for a tooth” may prevail in this stage of morality. During adolescence, conventional morality, level 3, becomes prevalent, with the view that there is a “right” and a “wrong” determined by society, often without the possibility of mitigating or extenuating circumstances. Adolescents espousing this level of morality are often rigid in their concept of “good” and “bad” and unable to find a role for motivation in their judgment of behaviors. Thus, adolescents may often take the viewpoint of applying the harshest punishments that society can offer when asked to judge complex moral situations—for example, a poor man robbing a pharmacy to obtain a life-saving medication for his child. Later in adolescence, at level 4, a greater understanding of societal rules may be espoused within the context of conventional morality. It is generally not until late adolescence or early adulthood that the complexities of moral decision making are recognized and incorporated into their thinking. Postconventional morality (level 5), according to Kohlberg, implies the ability to interpret complex moral dilemmas in which the best moral decisions of an individual may come into conflict with the moral standards of society. At this level of thinking, adolescents are more flexible in their understanding of “right” and “wrong.” The concept of extenuating circumstances is understood at this level of moral thinking, allowing exceptions to rules that are ordinarily followed. Kohlberg postulated a final, higher level of postconventional moral development that he labeled level 6, in which an individual is able to recognize a universal moral imperative that might take priority over standard societal moral values.

Although Kohlberg’s and Piaget’s notions of moral development focus on a unified theory of cognitive maturation for both sexes, Carol Gilligan emphasizes the social context of moral development leading to divergent patterns in moral development. Gilligan points out that, in women, compassion and the ethics of caring are dominant features of moral decision making, whereas, for men, predominant features of moral judgments are related more to a perception of justice, rationality, and a sense of fairness.

Self-Esteem

The proliferation of social media since the 1990s has provided opportunities for adolescents to engage in social interactions with peers across the globe. These interactions have enabled adolescents to broaden their social connections when they feel isolated, to seek support when they are experiencing distress, and to learn about other adolescents and their interests. This has been a positive experience for most adolescents as they engage in social and interpersonal challenges. In some cases, however, particularly for adolescents who are vulnerable, at-risk for emotional problems, or have pre-existing mental health conditions, their self-esteem may be compromised. Epidemiologic surveys suggest that the majority of adolescents meet the challenges of their physical, social, and emotional development with optimism and solid self-esteem. Self-esteem is a conglomerate measure of one’s sense of self-worth based on perceived success and achievements, as well as a perception of how much one is valued by peers, family members, teachers, and society in general. The most important correlates of good self-esteem are one's perception of positive physical appearance and high-value to peers and family. Secondary features of self-esteem relate to academic achievement, athletic abilities, and special talents. Adolescent self-esteem is mediated, to a significant degree, by the positive feedback received from a peer group and family members, and adolescents often seek out a peer group that offers acceptance, regardless of negative behaviors associated with that group. There are also developmental factors that influence adolescents' cognitions about themselves that affect global ratings of self-esteem in this age group. Studies comparing reported self-esteem across the lifespan indicate that there are trends in self-esteem ratings that are age-related. Starting in adolescence, there are also gender differences in reported self-esteem. A study investigating global measures of self-esteem in school-aged children—adolescents, 13 to 17 years old, and older teens to young adults, 18 to 22 years old—found group differences depending on age. Overall, reported self-esteem was found to be highest in school-aged children as compared to adolescents and young adults, and boys and girls were identical in their self-reports. During adolescence, global reports of self-esteem decreased throughout, with adolescent girls experiencing a drop twice that of adolescent boys. Self-esteem, at a group level, continued to drop during the high school years, rose in young adulthood during the college years, and continued to rise in early to midadulthood. Girls continued to rate themselves with generally lower self-esteem into adulthood. The question arises as to how most adolescents surveyed report relatively good adjustment and yet, at the same time, experienced a drop in self-esteem. These data appear to reflect the "inflated" self-esteem of school-aged children, who may be seeing themselves as better, smarter, and more capable than they really are. During adolescence, it is quite possible that even well-adjusted individuals realize that they are not as exceptional as they used to believe they were. Adolescents seem to be more aware of their shortcomings and, therefore, had lower self-reported scores on self-esteem measures. In young adulthood, however, and into midadulthood, along with expanded cognitive abilities for self-regulation, reported self-esteem increases, and continues to increase well into midadult life.

ADOLESCENT BRAIN DEVELOPMENT: CORRELATIONS WITH EMOTIONAL, SOCIAL, AND COGNITIVE CHANGES

It is now widely accepted that emotional, social, and cognitive brain processes continue to develop throughout childhood and early and late adolescence. The structural and functional development of various regions of the adolescent brain interacts with the social environment to influence social sensitivity, cognitive decisions, and risk-taking behaviors.

The work of Blakemore and Mills and other researchers have consistently suggested that a network of specific brain regions is involved in social cognitive processes. For example, an adolescent's increasing ability to understand the mental states and, thereby, the behaviors of others, "mentalizing," also called "theory of mind," has been associated with a network of brain regions, including the dorsal medial prefrontal cortex (dmPFC), the TPJ, pSTS, and the anterior temporal cortex (ATC). These brain gray matter regions have been shown to continue to develop in volume, cortical thickness, and surface area throughout adolescence before stabilizing in young adulthood. During adolescence, the overall gray matter does not mature by growing larger. Instead, it is pruned to be more specialized. However, the PFF, parts of which are involved in mentalizing and other portions with judgment, impulse control, and long-range planning, continue to undergo dynamic changes into the early 20s.

A variety of tasks-related to mentalizing, such as recognizing the meaning of facial expressions, have been shown to activate the mPFC, and in fact, this brain region has also been shown to become diminished in size and more specialized between late adolescence and adulthood. Social emotions such as embarrassment, shame, guilt, and pride require an understanding of what others may be thinking or feeling (mentalizing) about someone, whereas fear does not. In adolescence, increased sensitivity to peer opinions is a hallmark trait, and the corresponding brain regions in adolescents may be activated. Functional MRI (fMRI) study investigating neural activation during tasks related to viewing or reading social-emotional scenarios found that adolescents recruited the dmPFC even more intensely than adults given the same tasks.

In a recent study of an online communication game requiring the subject to understand the mental state of the online player in order to make correct decisions, a midadolescent group made less mistakes than a midchildhood group, but more mistakes than a young adult group. This result supports the notion that social development is still in play and not maximized even in late adolescence and that social sensitivity and social skills increase into young adulthood.

On the other hand, brain regions associated with risk-taking and sensation-seeking include the amygdala, nucleus accumbens (NAcc), and PFF. A study investigating the time course of maturation of the brain regions associated with risk-taking behaviors found that relatively earlier maturation of the amygdala and/or the NAcc compared to the PFF suggested a mismatch between these structures. The amygdala has been found to increase in volume from late childhood until mid to late adolescence with less growth after the age of 16 years. On the other hand, the PFF showed little change in gray matter volume in childhood and continues to decline into young adulthood. More research is needed in order to draw conclusions about adolescent risk-taking behaviors and sensation-seeking in view of these differentially developing brain regions.

In contrast to gray matter, white matter volumes increase throughout childhood and adolescence and reflect a developing integration or “connectivity” of brain function regions that are myelinated.

During the course of adolescence significant qualitative changes in thinking are demonstrated in greater ability to discriminate emotional cues, increased self-awareness, selective attention to information, and increased response inhibition. Perhaps the most dramatic changes in cognitive abilities are an increased capacity for abstract reasoning, planning, and affect modulation. Over the past two decades, MRI and fMRI have become important modalities for studying both the structure and the function of adolescent brains. Two areas of the brain consistently shown by MRI to evidence structural changes during adolescence are the PFF and the parietal cortex. Neuroimaging studies indicate that the PFF matures more slowly than other areas of the brain and that its development is correlated with increased capacity in adolescents to inhibit behavioral responses. The PFF is known to mediate “executive function,” that is, skills involving working memory, selective attention, and voluntary response inhibition. In addition to executive function, the PFF is believed to be involved in social and cognitive abilities such as self-awareness and the development of an understanding of another person’s perspective. Recent studies have provided evidence of a linear improvement in performance by age on certain tasks within executive function, such as those involving selective attention, working memory, and problem solving. This lends support for an increase in performance in these tasks as a function of the pruning and synaptic reorganization of the PFF.

Social cognition—in particular, recognition of facial expressions of emotion—has been studied in healthy adolescents. The amygdala, a region of the brain known to be associated with emotion processing, was found by fMRI to be activated in adolescents shown fearful facial expressions and in response to happy faces compared to neutral faces. Among adolescents, left amygdala activity when presented with fearful faces decreased in girls but not in boys. Female adolescents also demonstrated greater activation of the dorsolateral PFF, whereas male adolescents did not show this pattern. It was hypothesized that the pattern of diminished amygdala and increased prefrontal activation in female adolescents reflects increased maturity in the regulation of emotional experiences in them compared to male adolescents. Structural and fMRI studies implicate puberty as a period of synaptic reorganization in the prefrontal and parietal cortex, which may place the adolescent brain in a sensitized state with respect to the development of executive functions and social cognitive skills. Clearly, the adolescent brain continues to develop structurally, and the relationships of these structural changes to behavioral and emotional responses warrant further investigation.

CURRENT ENVIRONMENTAL INFLUENCES AND ADOLESCENCE

Adolescent Sexual Behavior

Sexual interest and experimentation are critical components of adolescent development for boys and girls. Sexual experimentation in adolescents often begins with fantasy and masturbation in early adolescence, followed by genital touching with the opposite sex or, in some cases, same-sex partners, oral sex with partners, and initiation of sexual intercourse at a later point in development. In one study of urban adolescents, at least one-third reported some form of genital sexual activity in the last year with a partner, and approximately 10% reported oral sexual behavior with a partner. The balance between healthy adolescent sexual experimentation and emotionally and physically safe sexual practices has been one of the major challenges for society in the new millennium.

Trends in adolescent sexual activity are monitored by the YRBSS, which measures the self-reported prevalence of health-risk behaviors, including sexual activity. Surveys obtained for the years 2018 to 2019 provide detailed information regarding sexual activity in adolescents and the risks associated with these behaviors. Among high school students across the nation, 38.4% reported that they had had sexual intercourse during their life, and 27.4% of high school students reported that they were currently sexually active. Among those who were currently sexually active, 45.7% reported that they or their partner hadn’t used a condom during their last sexual intercourse. The prevalence of having had sexual intercourse at least once was higher among black males (50.1%) than Hispanic males (43.6%), followed by Hispanic females (40.3%), and black females (34%). The overall rate of having had sexual intercourse in high school among white students was 38.2%, with white females (39.2%) reporting it more frequently than white males (36.7%). A total of 8.6% of students report that they had had sexual intercourse with at least four persons during their lifetime. Among the 27.4% of currently sexually active students nationwide, 45.7% reported that either they or their partner hadn't used birth control pills as a contraceptive before their last sexual intercourse. Prevalence of condom use at last sexual intercourse was 54.3%, and condoms were the most prevalent primary contraceptive method, a decline from the recent high of 63% in 2003. According to the CDC, the percentage of schools where students are required to receive instruction in HIV prevention decreased from 64% in 2000 to 41% in 2014. Nationwide, 9.4% of students had been tested for HIV. In 2018, 21% of new HIV cases were among youth. Statistics show that by the end of 2016, 51% of youth living with HIV were unaware that they had HIV.

Factors That Influence Adolescent Sexual Behavior. Factors impacting sexual behavior in adolescents include peer groups, psychosocial factors, temperamental and personality traits, externalizing and internalizing psychiatric symptoms, gender, cultural and religious background, racial factors, family attitudes, and sexual education and prevention programs.

A recent study has associated the role of low self-control, specifically impulsivity, with early sexual initiation and risky sexual behaviors, including sex while intoxicated, infrequent use of condoms, engaging in sex with strangers, a history of sexually transmitted diseases, and having multiple partners.

Longitudinal studies have also shown that a childhood history of aggressive-disruptive behaviors is associated with early sexual initiation and increased rates of adolescent sexual activity among boys and early initiation, increased teen pregnancies, and multiple sexual partners among girls.

Historically, male adolescents have initiated sexual intercourse at a younger age than female adolescents, and the 2019 YRBSS report revealed that 3.9% of boys and 2.1% of girls had sexual intercourse for the first time by age 13; the median age of sexual initiation was found to be 16 years of age for both males and females. Child Trends showed that the age at which sexual activity occurs among teens increases with grade level; 16% of ninth graders reported they were sexually active compared to 46% of 12th graders. In general, adolescents who initiate sexual intercourse at younger ages are more likely to have a greater number of sexual partners.

There is a suggestion from surveys of adolescents that early initiation of sexual intercourse before the age of 15 years is more frequent among African-American boys than in Hispanic boys and more frequent in Hispanic boys than in white boys.

Communities with high levels of trust and that offer youth opportunities like after-school programs, job training, and sports help young people avoid risky sexual behaviors, pregnancy, and support positive sexual health. Additional Protective factors include school and family connectedness, academic achievement, parental monitoring, a supportive and responsive parenting style, higher family income, spirituality, and religious affiliation, having plans for a positive future, and believing in the ability to control one’s life. Students who participate in well-designed sexual health education programs delay the initiation of sexual intercourse, have fewer sex partners, have fewer experiences of unprotected sex, and increase their use of protection, specifically condoms.

Risk-Taking Behavior

Risk-taking behaviors are typically the product of cumulative contributions from brain development in particular regions of the adolescent brain and social and environmental influences. These contributions include the possibility of overactive reward-related circuitry, as in the ventral striatum, as well as the influences of peer acceptance. In experimental circumstances, adolescents may rate the potential reward of a risky action as inflated. However, at times adolescents also rate the relative risks of actions as inflated.

Reasonable risk-taking is a necessary response to increasing autonomy in adolescence, leading to confidence in forming new relationships and competence in sports and in social situations. However, high-risk behaviors among this generation of adolescents are associated with serious negative consequences and can take many forms, including drug and alcohol use, unsafe sexual practices, self-injurious behaviors, and reckless driving. Alcohol is the most commonly used substance among adolescents and is associated with a multitude of coexisting high-risk behaviors, such as motor vehicle accidents resulting in injury and death, academic deterioration, aggressive behavior, and criminal behaviors. According to the National Institute on Alcohol Abuse and Alcoholism, in 2019, 4.2 million young people reported binge drinking (defined as at least five consecutive drinks at one time) at least once in the past month, and 8,25,000 reported binge drinking on 5 or more days over the past month. While the current use of alcohol has decreased over the last decade, binge drinking continues to be a problem. Historically, adolescent boys were more likely to drink alcohol and binge drink, but there has been a significant increase in both behaviors among teen girls compared to teen boys in recent surveys. Adolescents frequent and heavy use of alcohol was associated with future antisocial behavior, as well as increased levels of depression. Furthermore, even lower levels of alcohol use predicted similar problems as teens entered young adulthood. This implies the need for preventive interventions during adolescence for those teens who use alcohol, even if drinking behavior does not appear to be frequent or serious.

Illicit drugs, including marijuana, cocaine, heroin, hallucinogens, “ecstasy,” and amphetamines, also pose serious health risks among adolescents. Monitoring for the Future National Survey indicated that 8.7% of 8th graders used an illicit substance in a given month, and 18.22% and 22.22% of 10th and 12th graders, respectively, used illicit drugs in a given month. In younger adolescents, boys and girls had similar rates of drug use, whereas older adolescent boys had higher rates, especially among 11th and 12 graders. Although there are vast differences between adolescents who had experimented on rare occasions with marijuana and adolescents who engaged in daily drug use, the large numbers of adolescents engaged in these behaviors at every level is cause for public health concern. Furthermore, the use of illicit substances is also associated with youth crimes and violent behaviors. According to Child Trends Data Bank, in 2016, the rates of violent crime victimization (which include aggravated and simple assault, robbery, and rape) among adolescents aged 12 to 20 had fallen to 28 victimizations per 1,000 from 181 per 1,000 in the mid-1990s. Adolescents are most often the victim of simple assault; in 2016, 76% of adolescents aged 12 to 14 and 67% aged 15 to 17 were victims of simple assault. Male adolescents, ages 12 to 17, are more likely than female adolescents to be the victims of serious violent crimes, with the exception of sexual assault and rape. Younger male adolescents aged 12 to 14 are also more likely to be victims of violent crime than their older counterparts, 15 to 17 years old. These grave statistics indicate a need to identify risk factors and find protective factors for today's youth.

Identifying adolescents with high-risk behavior is not always feasible until the high-risk behaviors have resulted in academic or legal consequences. Once this occurs, a given adolescent can be identified as being at "high risk" for future difficulties and, optimally, should be monitored by a counselor through school, an outside therapist, and, in some cases, through the legal system. It is not always easy for an outsider, at first glance, to separate adolescents engaging in normal experimentation from those embroiled in high-risk behaviors. When there is evidence that an adolescent is engaged in frequent alcohol or drug use, reckless behavior, or criminal activities, urgent psychosocial interventions are needed. In less obvious cases, adolescents who have ongoing academic difficulties, do not participate in any athletic or other extracurricular structured activities and are socially isolated may also be in need of psychiatric evaluation.

A study in Pediatrics showed that high-risk behaviors (which include sexual intercourse, substance use, violent behaviors, and school problems) were strongly associated with the presence of tattoos and body piercings in adolescents. Both piercings and tattoos have become more mainstream among adolescents over the years. Recent studies show that approximately 10% to 23% of adolescents have tattoos, and 2% to 42% have body piercings; 27% of adolescents aged 16 to 18, and 11% aged 13 to 15 have asked their parents for a tattoo. Both tattoos and body piercings were more common in girls than in boys (16.6% vs. 8.1% for tattoos, 36.7% vs. 10.1% for body piercing). Adolescents who endorsed possession of at least one tattoo or body piercing were more likely to endorse the use of gateway drugs (cigarettes, alcohol, marijuana), as well as experience with hard drugs (cocaine, crystal methamphetamine, and “ecstasy”). Female adolescents who had tattoos or body piercings, especially younger adolescents, were more likely to endorse a history of suicidal ideation or behaviors. Male adolescents with tattoos and female adolescents with body piercings were more likely to report a history of involvement in physical fights, carrying a weapon, or bodily injury as a result of physical fighting. Adolescents with tattoos or piercings were more frequently sexually active than adolescents without them and at greater risk for unsafe sexual behavior.

Adolescents may choose clothing, hairstyles, and/or body decorations as a means of fitting in with a selected peer group or to attract attention and distinguish themselves as special or different from others. The presence of tattoos or body piercings does not necessarily indicate high-risk behaviors in adolescents. However, in certain peer groups, it is associated with risky lifestyles. Conversely, many adolescents with serious high-risk behaviors do not possess tattoos or body piercings. Given the serious consequences of alcohol and drug use and violence among adolescents, inquiry into these behaviors should be an integral part of every health care evaluation.

Adolescent Use of the Internet and Social Media

The internet and social media are ubiquitous among adolescents and serve as platforms to socialize, communicate, and share talents, as well as a myriad of personal information, affecting all aspects of life for today’s adolescents. The “digital revolution” the explosion and integration of multiple technologies into daily life) among adolescents, as discussed by Giedd (2012), has highlighted the adaptive nature of the adolescent brain in its ability to embrace and incorporate these technologies. According to Giedd, the amount of time it took for 50 million users to develop (pace of “penetration”) with respect to older technologies such as television was 13 years. However, for newer technologies, the pace of “penetration” is moving at record speed. For the internet, it was 4 years; for Facebook, it took about 3½ years; for

Twitter, about 3 years; for iPads, 2 years; and for Google+, it took only 88 days to gain 50 million users!

Recent reports indicate that about 90% of children and adolescents use the internet in myriad ways, including instant messaging, visiting social networking sites, blogging, chatting in chat rooms, posting photos, videos, and stories, and obtaining information by visiting numerous websites. Positive effects of the internet identified for adolescents include exponentially increased communication with both friends and family and increased access to academic information, and familiarity with the social and cultural habits of people around the world. Concerns raised regarding teens' access to a constant and overlapping barrage of stimuli, however, include the ubiquitous "multitasking" that seems to characterize adolescent practices in the United States. While adolescents may be under the impression that doing their homework while chatting with a friend, listening to music, instant messaging, and viewing Facebook seems like an efficient way to get more done in the same amount of time, however, the brain is actually rapidly shifting between tasks leading to interruption of attention to potentially vital tasks. For example, an MRI study of a simulated driving task with or without competing stimuli showed significant impairment in driving performance during competing conversation, in addition to a sizable reduction in activation in the parietal lobe.

Some adolescents use the internet to learn about health-related issues and for self-help. In this regard, several health-related, adolescent-friendly websites are available that provide information on a variety of psychological and medical topics. One such site is http://www.teenshealth.org, a U.S.-based website, provides information about general and healthy living information for kids, teens, and parents, including information on mental health, sexual health, causes of illness, a question and answer section, and information on different coping skills. Mind Your Mind (http://mindyourmind.ca) is a Canadian website for youth by youth, which provides resources to help teens manage their stress and mental health issues and includes personal stories, music, videos, toolkit, and a blog. Safe Place (https://www.nationalsafeplace.org/for-teens) is a national youth outreach and prevention program for young people under age 18 who need immediate help and safety. Mental Health Literacy (https://mentalhealthliteracy.org/) is another Canadian website where, friends, parents, health professionals, and educators can help support teens. There are significant risks associated with Internet use, especially for adolescents who share personal information and communicate with strangers on line. According to the National Cyber Security Alliance (NCSA), a national survey that sampled 804 online teen users between the ages of 13 and 17 years showed that American teens have had hurtful and complicated online experiences which include negative messages about things they have said or done, their appearance, sexual orientation, and gender or race or ethnicity. Thirty-nine percent of teens reported that someone had been mean or cruel to them while online or while using apps over the past year. Many teens were "very concerned" about having someone post untrue things about them online (35%), receiving unwanted communications that made them uncomfortable (32%), and being pressured to participate in harassing or bullying someone else (32%). Online teens also said that they were very concerned" about being harassed or bullied for a sustained period themselves (29%), being approached by people they don't know online (25%), and being called offensive names (25%). The 2014 Teen Internet Safety Survey revealed 54% of teens had witnessed cyberbullying online, 24% reported being bullied online, 60% who were bullied told an adult. One study showed that cyberbullying and victimization begin as early as second grade, peaking in middle school when the online exchange of sex-related content begins; and behaviors typically increase into the high school years. Internet safety programs urge youth to avoid sharing personal information and not to communicate with strangers online. It is also crucial that parents play an active role in keeping their children and adolescents safe online, emphasizing supervision.

It is clear that adolescent culture in the United States is dominated by technology in a variety of ways and is a vital part of teen social interactions. Social media technologies have enabled adolescents to connect with a vastly larger scope of other teens than they could meet in daily life. Teens are not necessarily more or less social due to social media, however, the opportunities are broader to interact with more people using more diverse modalities.

Child Psychiatric Examination

35.1 Psychiatric Examination of the Infant, Child, and Adolescent

ROBERT A. KING, M.D., PRUDENCE W. FISHER, PH.D., MICHAEL H. BLOCH, M.D., M.S., MARY SCHWAB SELIGMAN, M.D., M.A.R., WALTER S. GILLIAM, PH.D., AND MICHAEL VITULANO, PH.D.

Clinical diagnostic assessment of youth includes identification of the reasons for referral, evaluation of the nature and extent of the child's emotional or behavioral difficulties, and determination of factors in the child, family, and environment that cause, exacerbate, or potentially ameliorate them. Although information gathering and differential diagnosis are the primary aims of assessment, an ancillary goal of the evaluation process is to facilitate the development of an alliance between the clinician and the family.

Psychiatric assessment of the child or adolescent is undertaken for a variety of purposes, including outpatient office or clinic evaluation to determine the need for treatment; emergency department assessment of safety issues and need for hospitalization; consultation with pediatric, school, or legal services; as a component of family or other treatment modalities; and for research purposes.

Although the structure and style of the assessment vary to some extent depending on the purpose and setting, certain elements are common to all such assessments.

Decisions about intervention follow from evaluation, so clinical assessment may rightly be regarded as a cornerstone of child and adolescent psychiatry. Clinical evaluation of the child or adolescent may be challenging and complex in that the clinician must draw on multiple sources and a range of clinical techniques for eliciting information on various aspects of the child's functioning. This information must then be integrated using the clinician's knowledge of development and psychopathology, cultural sensitivity, and context of the symptoms to arrive at a diagnostic formulation that can guide effective treatment planning.

The initial portion of this chapter focuses on the comprehensive clinical assessment of the child and adolescent; subsequent subsections discuss more specialized types of assessment, such as the assessment of infants and adolescents, psychological testing, laboratory assessment, and clinical research assessment instruments.

CLINICAL INTERVIEW OF THE CHILD

The psychiatric assessment of the child requires a comprehensive approach that evaluates the child's developmental progress in various domains and positive adaptive capacities, as well as the presence of the pathognomonic symptoms of specific disorders. A developmental approach to the assessment of the child is essential because children differ from adults in certain key respects.

Distinctive Features of Childhood Psychopathology

First, psychiatric disturbances in children often consist of a lack of developmental progress in one or more domains rather than the presence of specific symptoms that are pathognomonic of adult disorders. For example, a nursery school child's failure to develop useful social language or interactions or a school-aged child's inability to meet the developmental expectation of separating from parents and settling into the school day may prompt an assessment.

Second, the child’s developmental status may affect the clinical presentation of various symptoms and syndromes. For example, in children, depression often presents with irritability and somatic complaints, whereas excessive guilt or depressive delusions are rare.

Third, development brings expectable periods in which distressing emotions or behavior may occur as part of a normal transition, for example, the separation anxiety of a child starting preschool or the oppositionality of the adolescent.

In many cases, clinical conditions represent severe forms of symptoms found in milder form in most children. Fears, tantrums, moodiness, or restlessness are relatively common in childhood and occur transiently at different stages. Assessment may be sought by concerned parents seeking guidance on how to understand and manage these developmental manifestations. Thus, the clinician must judge whether the behavior is likely to resolve with time and without substantial deleterious effect on the child or family or whether, instead, the level of distress, compromised functioning, or symptom persistence indicates the need for clinical intervention.

To distinguish transient or normative difficulties from those that are more clinically worrisome, the evaluator must have a solid knowledge of typical and atypical child development. This developmental frame of reference includes an understanding of what behaviors can be expected in children of different ages, the time frame within which various behaviors normally wax and wane, the natural history of psychiatric disturbances at different stages in development, and at what age particular syndromes are likely to emerge.

Many children coming to clinical attention have symptoms that cannot be neatly subsumed under the rubric of a single diagnostic label. Comorbidity is usually not the exception but the rule in childhood disorders. Even in epidemiologic studies of children and adolescents, as many as one-half of those who meet diagnostic criteria for one disorder also meet criteria for at least another disorder. This high rate of comorbidity, found even in nonreferred populations, has several likely sources. Many traditional nosologic entities draw their definition from clinical experience with adults; although childhood analogs clearly exist, the appropriate descriptive boundaries may not be the same. Furthermore, impairing symptoms in childhood tend to have a ramifying effect by interfering with the ongoing acquisition of key developmental skills in multiple areas. Finally, regardless of whether the origins of a given form of childhood psychopathology lie in biologic factors, family or social environment, or interactions among these realms, these forces often produce symptoms that cut across many diagnostic lines.

Distinctive Aspects of Child Assessment

Most adults coming for psychiatric assessment acknowledge at least some degree of self-perceived distress and wish for help. In contrast, for most children, the responsibility for initiating and following through with a psychiatric evaluation lies with the parents. In many cases, the child's behavior is a greater source of concern for others—parents, teachers, and peers—than to the child him- or herself. Other children, even while acknowledging distress, may view the locus of the troubles as purely external and hence see little need for evaluation, even if they comprehend the process. In any event, the lack of any stated wish for help or active role in seeking the evaluation colors the child assessment process from the start. As a result, explicit attention must be paid to assessing the child's view of the problem and cultivating the child's engagement in the process.

A related aspect of the child psychiatric assessment involves the need for the clinician to assess and accommodate to the limitations in the child's ability to reflect, to conceptualize, and to report experiences and internal states. These capacities emerge only gradually with maturation and are influenced by normal and pathologic factors. Thus, the clinician's communication must be attuned to the child's developmental level and may require play, stories, drawing, and other alternative modes of interaction in addition to direct discourse.

Context and the Need for Multiple Informants

Even more so than for an adult, the child’s functioning and psychological well-being are strongly related to the social context—the family, school, and community settings—in which the child lives and develops. Thus, to evaluate the nature and severity of the child’s psychiatric status, information is needed about the child’s relationship to, and functioning in, these diverse settings. The fit of the child and social environment can be appraised from what parents or primary caregivers say about their relationships with the child and from the child’s direct report, as well as from play and drawings; however, direct observation of the content and tone of parent–child interactions in the office setting also provides much useful additional data. In some cases, a home visit may provide invaluable information.

It is also important to gather information on the child’s functioning in school, a task that optimally includes speaking with the child’s teachers in addition to reviewing school reports and educational assessments. Here, too, direct classroom observation can provide invaluable in vivo information. For children involved with child welfare, juvenile justice, or other institutional systems, information from caseworkers, probation officers, and residential treatment caregivers is essential.

Special Types of Assessment

The main emphasis of this section is on the assessment of children and adolescents, especially those capable of participating verbally in the assessment process. Because developmental considerations shape the evaluation process, infants and toddlers, on the one hand, and adolescents, on the other, require specific modifications of the general approach outlined in this section. Nonverbal or children with language deficits, such as those with developmental disorders or intellectual disabilities, require specialized assessment techniques.

Although the prototype for clinical assessment of the child is the office consultation or clinic visit, evaluations occur in a variety of settings, including schools, pediatric wards, residential treatment centers, detention centers, and hospital emergency departments. Procedures necessarily vary with the setting and reasons for carrying out the assessment. The following general model for the outpatient evaluation can be adapted to fit more specific clinical situations. More specialized types of evaluation, such as those for epidemiologic or research purposes, are discussed later in separate subsections.

Preliminary Contact

In the initial phone call to the clinician or clinic intake office, it is helpful to gather some basic information about the nature of the chief complaint; to set the time, date, and place of the first appointment; and, if relevant, to discuss issues of fee or insurance coverage.

During the evaluation, the clinician will optimally see the parents alone, the child alone, and the parents and child together. The order in which these should be done and who attends the first meeting should be discussed at the initial contact. This decision is usually made with reference to the child's age. When evaluating a young child, the parents are often seen first, without the child. This allows the clinician to obtain a history and discuss how to prepare the child for the evaluation. The adolescent should usually be included in the initial interview or seen first so that the youngster does not identify the clinician as an agent of the parents, which may interfere with their willingness to talk and impair the formation of a treatment alliance with the adolescent from the start. If children or adolescents are to attend the initial appointment, the clinician should discuss how they are to be prepared for the appointment in the initial call.

In the initial phone contact, the issue of which adults will attend should also be discussed. When the family is intact, the presence of both parents or caregivers is optimal. When this is not the case, the clinician and parent should discuss whether a noncustodial parent, stepparent, or other adult should be present.

Parent Interview

In the initial parent interview, the clinician seeks to understand the parents' view of the problems that have led to the referral, including the nature of the child's current difficulties, the explicit and implicit reasons for the timing of the referral, and the effect of the child's difficulties on the parents, individually and as a couple, and on the well-being and functioning of the family as a whole. A detailed history of the child's development and a review of family medical and psychiatric disorders are obtained. Finally, the clinician seeks to understand how the family is functioning in its community and cultural setting. This includes a careful appraisal of the strengths of the child and the family, in addition to the history of the presenting symptoms and areas of impairment.

Child's Current Difficulties and Reasons for Referral. In child psychiatry, referrals are usually initiated by the parent or parents rather than the child. Similarly, parents are key in determining whether a recommendation for treatment is followed. Over and above the need to gather information about the child's symptoms and functioning, the parent interview provides an opportunity to develop an alliance with the parents around the goals of identifying and helping the child's difficulties. Success of this process requires understanding the parents' expectations and concerns regarding the evaluation and its outcome. How these issues are addressed depends on the nature of the child's problems and the parents' knowledge of and previous experience with psychiatric evaluations and treatment. Attention to the parents' view of the evaluation process allows the clinician to address unrealistic fears or excessive expectations about what can be accomplished in a given time and to reduce family stress when parental anxiety is too high.

In taking a history of the current problem, the clinician obtains a detailed picture of the parents' current emotional and behavioral concerns about the child. Parents should be asked to describe specific instances of the child's problematic behavior, frequency, intensity, duration, circumstances in which the behavior occurs, their responses, and the child's responses to it. The extent to which the symptoms cause functional impairment is ascertained by asking about the level of the child's distress, interference with social and academic activities, effect on ongoing development, and the impact of the child's behavior on others. Parental responses to manifestations of the child's distress also require careful inquiry. Do the parents respond supportively, judgmentally, or punitively and are the parents in accord or at cross-purposes in responding to the child's symptoms? Do the parents' responses encourage the child's active coping or, say in the case of overly anxious or somaticizing children, do parents over-accommodate or inappropriately truncate expectations to spare the child distress, but in such a way that inadvertently increases avoidance and apprehension on the child's part? The clinician should also inquire directly about behaviors or symptoms not reported by the parents but known to be commonly associated with the presenting problem or with disorders that the presenting problem may suggest. Thus, one goal of the initial parent interview is to develop a detailed picture of the presenting problems, their course, their impact on the child's and family's functioning, and what has been tried to help alleviate them.

The clinician is also interested in the implicit and explicit reasons that the child has been brought for help at this particular moment. Often, the reason lies in an escalation of troublesome behavior or in the deleterious effect of a deficit emerging into sharper relief (e.g., a learning disability or attention deficit becoming more apparent as the child faces the increased demands of a new grade). In other cases, the child's behavior may not have changed, but a stressor within the family may have made it more difficult for the parents to manage bearable behavior. The factors propelling families to seek clinical attention are often complex. In surveys of the general child population, rates of diagnosable psychiatric disorders approach 20%, yet the number of children actively seeking or receiving clinical services is far lower. Multiple barriers may delay or inhibit psychiatric evaluations, including cultural ones, such as different understandings of emotional problems, a lack of diversity among mental health providers, or feelings of stigma or embarrassment; lack of funds or insurance may also contribute.

Throughout the history taking, the clinician strives to understand the meaning of the symptoms in relation to the specific factors in the child and the environment that influence them. A given symptom (e.g., a theft, a period of anxiety, or hallucinations) may have quite different meanings and clinical implications in different children and in children at different developmental periods. Thus, detailed information on precipitating circumstances, behavioral concomitants, and consequences and alleviating factors is needed, much as is the case in taking a medical history. However, this information must be interpreted within the broader developmental and family contexts in which the symptoms occur; thus, while gathering history, the clinician simultaneously takes in information about these contextual elements. History taking and diagnostic formulation are not distinct processes; during the interview process, clinicians continually formulate and test tentative hypotheses that guide further questions and the diagnostic possibilities under consideration.

To understand the child's presenting problems, developmental status, and family and social context, the clinician must learn about the child's strengths, interests, talents, and areas of adequate or superior adjustment. Such information is essential for a full diagnostic understanding of the child and helps the clinician to appraise the child's overall adjustment and functioning. Moreover, in planning for treatment, factors that may help to counterbalance or remediate the child's vulnerabilities must be identified. Finally, the clinician's appreciation and discussion of the child's strengths and areas of good functioning provide support and reassurance at a time when the child's problems and limitations have been the parents' major focus of attention.

The parent interview should also cover the practical and administrative aspects of the diagnostic assessment, including discussion of fees, scheduling, confidentiality, and, if applicable, permission to obtain information from school personnel and other clinicians. If the child was not included in the initial interview, the clinician should discuss appropriate preparation of the child for a meeting.

Developmental History. The developmental history is a detailed accounting of the child's development across physical, cognitive, linguistic, social, and emotional domains. One task of this part of the parent interview is to ascertain the timing and sequence of developmental events from pregnancy to the present. Parents vary in their ability to provide precise information on the timing of specific milestones; however, an adequate sense of the course of development can often be obtained by having the parents compare the patient's progress in a particular domain with that of siblings or peers. Asking parents about the timing of changes in the family, such as moves or other memorable life events, may help to provide a chronologic framework for remembering features of the child's development. Besides gathering descriptive information about the child's development, this part of the interview often allows one to tap the emotional aspects of the parent–child relationship by querying the parents' hopes, worries, expectations, and life circumstances in relation to different developmental events.

It is useful to conceptualize the child's past and current development in the following domains: *cognitive and academic development; family relationships; peer relationships; physical development and medical history; emotional development and temperament; development of conscience and values; interests, hobbies, talents, and avocations; and unusual circumstances.*

COGNITIVE AND ACADEMIC DEVELOPMENT. The child's pattern of cognitive strengths and weaknesses should be traced from early childhood, including verbal and attentional skills. Although academic performance is important (including areas of particular strength and weakness), important information about aspects of emotional and social development also flows naturally from the discussion of how the child progressed from one school year to the next. Thus, in tracking cognitive development and academic success, one should ask about the child's ability to separate from parents and to attend school regularly, interpersonal relationships with peers and teachers, motivation to learn, ability to function independently, tolerance for frustration and delay of gratification, attitudes toward authority, and ability to accept criticism, among others. A grade-by-grade history of the schools attended can be obtained during this part of the interview, as well as the reasons for any changes. Whether the child has ever received a special education classification should be queried and the supporting evaluations, specific resulting classification, and accommodations and services agreed upon should be reviewed.

When the child’s behavior or progress at school is among the reasons for the psychiatric evaluation, one should obtain permission to communicate with the child’s teachers, counselors, or other school personnel and to review the school records, including results of standardized tests.

FAMILY RELATIONSHIPS. The parent interview should include assessment of how the child relates to each family member and how the child fits into the overall family system. The child’s reactions to major family changes should be noted (e.g., deaths; birth of siblings; marital separation, divorce, or remarriage; and changes in caretaking arrangements, custody, or visitation), as well as parental responses to those reactions. Compliance with family rules and standards should be queried, as should consequences when the child does not comply (i.e., the parents’ usual modes of discipline or limit-setting) and the child’s response to such interventions.

PEER RELATIONSHIPS. The clinician should gather information about how the child relates to peers, including the number of friends, preferences regarding age and gender of friends, and any major changes in peer group; the child’s satisfaction with these relationships; their relative reciprocity and stability; activities and interests shared with peers; and parents’ feelings about the child’s close peers or lack thereof. The parents’ perspective on the child’s social skills and deficits should be assessed, including their sense about any difficulties the child has in this domain. Episodes of bullying or being bullied, and the consequences thereof, should be specifically queried. For adolescents, this part of the history includes issues such as the capacity for intimate relationships, romantic interests, sexual activity, and concerns about sexual orientation and gender identity. The clinician should gather information about the child’s social media usage and peer engagement through interactive online gaming.

PHYSICAL DEVELOPMENT AND MEDICAL HISTORY. Assessment of physical development includes fine and gross motor development, toilet training and its lapses, eating behavior and attitudes, and sleep patterns. Precocious development or delays in physical growth or pubertal maturation should be noted, as well as the child's concerns and reactions. In this context, parents should be asked systematically about medication, illnesses, hospitalizations, emergency room visits, operations, episodes of loss of consciousness, seizures, head injury, or other serious injuries, as well as the child's reactions to these and their effect on subsequent health and activities. Inquiry about tics, difficulties with hearing or vision, lead exposure, and other specific conditions may be suggested by the clinical presentation. When necessary, medical reports should be obtained and reviewed.

EMOTIONAL DEVELOPMENT AND TEMPERAMENT. Although some aspects of emotional development and temperament will have been covered in taking the history of the presenting problems, the clinician should fill in gaps with a systematic review. This domain of assessment includes the child's present and past mood and capacity for emotional regulation, anxieties, and ability to adapt to changes and situations that are new, challenging, or frustrating. Prevailing mood as perceived by the parents should be assessed; the clinician should ask specifically about self-injury and suicidal ideation, gestures, or attempts, especially if the child has shown depressive symptoms, including irritability. Worries, fears, and other manifestations of anxiety should be covered, and the level of any distress and impairment should be explored. The generalized or specific nature of symptoms, situational evokers, historical precipitants, and effects on the child in terms of impairment or distress are relevant. It is also important to note unusual fears, excessive shyness or withdrawal, and obsessive or compulsive symptoms.

Emotional regulation (ER) describes the child's ability to manage emotional arousal (including negative affects related to frustration), an ability that develops over time, has both heritable and environmental components, and is influenced by attachment behaviors and caregiver responses. Irritability (elevated anger-proneness and persistence of negative mood relative to peers) is a form of *emotional dysregulation* that is emerging as a robust trans-diagnostic trait or dimension that is moderately persistent over the life-span and confers risk for future anxiety, depression, and impaired role functioning. Various research paradigms and instruments have been developed to assess and study this concept. Clinically, however, it can be assessed by inquiring about: (1) the types (and thresholds) of stimuli or situations that elicit negative affect on the child's part (what has been termed the *reactive* component of ER); (2) what sorts of strategies the child employs to reduce, balance, or recover from negative emotions and how successful these efforts are or not (what has been termed the *regulatory* component); and (3) the parents' role in helping the child with these coping efforts.

The child's capacity to regulate aggression falls within this domain and should be reviewed. The clinician should ask about circumstances in which the child becomes angry or aggressive, the child's mode of expressing anger (i.e., verbal, physical, or both), how this affects others, and the child's reaction to and processing of such feelings and behavior. In this context, the clinician seeks to evaluate how the child manages aggression and whether the child is too aggressive or too fearful of their anger or that of others. Specific aggressive symptoms (e.g., bullying, fire setting, vandalism, or cruelty to animals) should also be inquired after.

DEVELOPMENT OF CONSCIENCE AND VALUES. The clinician should assess the development of conscience to gauge whether it is too harsh, lax, or overly focused on particular issues. The effectiveness of conscience in helping the child conform to family and societal expectations is important. Religious or ethical concerns and their concordance with those of the family can be addressed in this phase of history taking. The family's expectations with regard to the child's values and future life choices should be ascertained from the parents' perspective, and areas of potential discord should be noted.

INTERESTS, HOBBIES, TALENTS, AND AVOCATIONS. Although this line of inquiry is routinely pursued with the child, it is useful to obtain the parents' perspectives on the child's interests and activities and to assess the parents' approval, involvement, and support for them. Indications of parent–child conflict should be probed and provide useful information about family relationships. The presenting difficulties may have affected the child's ability to focus on or to engage in previously necessary endeavors, such as completing schoolwork, and enjoyable areas of interest or activity, such as sports or music.

The quantity and type of mobile phone use and screen time approved by parents or caregivers—including social media, texting, television, and videogames—and the extent of any resulting conflicts about parent approval provide important information on the child's interests and the quality of parental supervision, monitoring, and limit setting.

CHILDHOOD ADVERSE EXPERIENCES. The clinician should assess for the child's experience of cultural discrimination or isolation, immigration, or exposure to traumatic events. The clinician should assess for a history of sexual or physical abuse, domestic or community violence, race-based trauma, natural disaster, or armed conflict. If a history of trauma exists, the child's immediate and subsequent reactions and the nature of the parents' or caregivers' response should be assessed. If a child or adolescent discloses a history of child maltreatment, such as physical or sexual abuse, neglect, or emotional abuse, which has not previously been reported, the clinician must report it to the appropriate local child protective service agency.

Family and Community Background. Children develop in the contexts of the family and community, and these provide opportunities and challenges that influence and shape the course of that development. The clinician should gain a picture of the child's functioning in these contexts and their influences on the child. Although the clinician learns a great deal about these areas from taking the history of the presenting problem and the developmental history, direct questioning may also be needed.

PARENTS. The clinician should assess the parents as individuals and as a couple, including strengths, weaknesses, and areas of conflict or difficulty. If the child resides with someone other than the parents (e.g., a relative or foster parent), the clinician should obtain information on the history and circumstances of that relationship, including how the child came to be in that adult's care. It is also necessary to determine what the child's previous experiences were with the parents and the nature of the bond with them. The clinician should similarly assess the current caregivers and their parenting relationship with the child.

If the child is adopted, information is needed on the circumstances, the parents' feelings and expectations about the adoption, the child's age at adoption, the child's adjustment at the time and later, and how the child and family members currently view the fact of the adoption. The clinician should also determine how the adoption has been discussed with the child and any concerns or questions about the biologic parents.

When taking the developmental history, it is often natural to inquire about the parents' feelings and involvement with the child at different stages. Parents' past attitudes and behavior are likely to shed light on their responses in the current situation; hence, one wants to know how they felt about past difficulties and what they have done to help and to support the child. The parents' individual views on the causes of the child's difficulties, and the extent to which they agree or disagree on this and other aspects of the child's care and management, affect how they respond to the clinician's recommendations.

The clinician should ask about the parents' cultural, ethnic, and religious backgrounds and traditions. These may be a source of shared identity and values to be imparted to the child or a source of conflict between the parents or between an adolescent and the parents. If the clinician is not very familiar with the culture or language of the family to understand the cultural context of clinically relevant aspects of the child and family's situation, an attitude of "cultural humility" is needed, and a respectful desire to know more about their culture should be conveyed. The clinician should guard against making assumptions about race, ethnicity, appearance, or preconceived notions about culture.

The parents' education and occupation may bear on how they understand and respond to the evaluation. How knowledgeable and worried they are may depend on their past experiences and familiarity with psychiatric issues. Financial resources and insurance coverage should be ascertained as these may be a source of stress or worry and thus pose practical constraints on the treatment options available to the family.

The clinician should gain an understanding of how the family system functions, with whom the child lives, and the nature of relationships between household members and the child. Other issues to explore are boundaries and alliances within the family and the child's affinities and conflictual relationships with parents, siblings, and other household members. Family communication and problem-solving styles should be assessed, including how issues of separation or disagreement are handled. The emotional tone of the family (e.g., tense, anxious, critical, competitive, warm, or supportive) can be ascertained by observing interactions and by direct inquiry. Stresses on the family as a whole or individual members (e.g., moves, migration, illness, accidents, job loss, or economic or legal difficulties) should also be addressed.

Adverse childhood experiences, beginning in utero, including separation, abuse, neglect, exposure to violence, poverty, and parental substance use or depression, have deleterious cumulative effects on the child's development over time. Long-term effects of adverse childhood experiences cross traditional diagnostic boundaries, impact development, and are known risk factors for multiple forms of medical, psychiatric, and social adversity in later life. These factors often operate across generations. Hence, information on the parents' backgrounds and histories with their own families of origin is essential to understanding their relationships with and responses to their child.

COMMUNITY. The clinician should understand the community or neighborhood in which the family lives and their feelings about and identification with it. Information on the family's involvement with civic, community, and religious activities (and the extent to which the child participates) should be ascertained. Is the family socially isolated by reason of discrimination, ethnicity/race, immigration status, or other forms of stigma (e.g., related to mental health or chronic illness)?

Learning from parents and adolescents about their neighborhood is critical, especially for a deeper understanding of the child and adolescent's environment. What is the family's housing like, and what options are realistically available? What is the level of residential segregation? How serious is crime or community violence, and how has it impacted the family directly or indirectly? What steps do the parents take to try to keep their child or teen safe? How are the police regarded in the neighborhood—as protective, potentially dangerously adversarial, or some admixture thereof? What has been the family's and child's history with law enforcement and the justice system? How do other neighborhood factors, such as lack of childcare, grocery stores, or access to transportation impact the family?

Numerous studies point to the centrality of social determinants of mental health issues for children and adolescents, especially the burdens on youth from marginalized groups, including racial and ethnic minorities. Many of these factors are community-based and reflect multi-generational histories of residential and educational segregation. These result in economic, educational, and healthcare disparities whose potential impact on the child and family must be considered and need to be assessed. These disparities can be considered under several headings: Economic instability; educational disadvantage; access to health care; neighborhood environment. Although these factors can be examined at the level of the individual parents and family, broader social determinants impact how a given family got there.

For example, inadequate household income, parental unemployment, and housing and food insecurity are fundamental problems with immense mental health implications for any given family. However, ameliorating the perpetuation of these risk factors for a family involves addressing broader community and social factors that are often difficult or impossible for a family to surmount, at least without local resources and advocacy that transcend those usually available in most clinical programs. Educational inequality is also often multi-generational, truncating parents' economic, vocational, and housing opportunities. These in turn impact their children, beginning with lack of access to early childhood education programs, adequate neighborhood schools, availability of tutoring and other academic assistance programs, and the absence of role models for academic success.

Stresses related to racial and/or ethnic discrimination can have a cumulative negative impact on parents and children. In addition to influencing factors such as housing, occupational, and educational discrimination noted above, racial traumas also include microaggressions, various forms of in-person and online harassment, and exposure to racial violence, either directly or vicariously via news or other media. Inquiring about the occurrence and impact of race-related stressors on the parents and youngster requires tact, training, humility, and clinicians' self-awareness of how their own racial identity, position of privilege, and potential unconscious biases influence how they interact with patients.

Beyond the parents' and family's own prior experiences with mental health services, community attitudes may strongly influence how the child and family approach a psychiatric evaluation. In some communities, mental health clinicians and agencies are viewed positively; in others, their use is stigmatized or viewed with suspicion as potentially racist or coercive, which may adversely affect the child. These issues should be assessed and understood because they may affect how and where the child receives any indicated treatment, how the treatment goals are formulated, definition of treatment type appropriate of the particular patient, and selection of provider best matched to the patient's needs. In some systems, it is unfortunately not possible to choose the ideal match for referral due to lack of resources.

The DSM-5 Cultural Formulation Interview (CFI) and its supplemental modules provide a cultural assessment tool that may help clinicians with this important task (https://www.psychiatry.org/File%20Library/Psychiatrists/Practice/DSM/APA_DSM5_Cultural-Formulation-Interview.pdf;

https://mn.gov/dhs/assets/supplementary-modules-cultural-formulation-interview_tcm1053-413785.pdf).

Family Medical and Psychiatric History. A careful family medical and psychiatric history is needed to identify any medical or psychiatric disorders with potential genetic or environmental implications for the child. Among those to be routinely considered are psychotic disorders, mood disorders, anxiety disorders, tic and obsessive-compulsive spectrum disorders, alcohol or substance use disorders, attention-deficit disorders, learning disorders, and antisocial personality disorder, as well as metabolic and neurologic disorders. The impact of any family members' symptoms, hospitalizations, or incarcerations should be probed, with particular reference to the child.

Special Issues in the Parent Interview

INFORMANT DIFFERENCES. Although parents' concerns usually play a major role in initiating the evaluation, parents may perceive the child's problems differently and may disagree about their severity and the need for treatment. Parents' accounts of the child's difficulties and of various aspects of the developmental history may not agree completely with each other or with those of the child, teachers, or records of past events. To note these discrepancies is not to denigrate the reliability of parents as informants but rather to emphasize the necessity of obtaining information from multiple informants.

Informants provide differing accounts of children's problems for various reasons and discrepancies should be noted and regarded as potentially useful data regarding what they reflect about the clinical situation. Informants may interact with the child in different settings that vary in the extent to which the child expresses disturbing feelings and problematic behavior. This is commonly true for behaviors expressed most dramatically in settings that challenge the child in vulnerable areas (e.g., the school's demand that a child with attention-deficit/hyperactivity disorder [ADHD] sit still and pay attention). Information about such situation-specific symptoms is best provided by those who spend the most time with the child in that setting (in this instance, teachers). These different perspectives on the child's behavior may also have led to tension between informants who see the child discrepantly. Discrepancies are often found between divorced or separated parents, whose child may show quite different behavior in the context of each parent's home. The clinician should be aware of these different perspectives and the feelings that they generate so that the focus is maintained on evaluating and providing services for the child, with adults working together rather than at cross-purposes.

Another reason for discrepant reporting involves differences in how the informants evaluate the child's behavior. Observers may judge the same behavior by differing standards or expectations for many reasons. The clinician's appreciation of the informant's psychology or cultural background is useful for understanding and working with such differences. For example, when one parent is overly worried about the child having a serious disorder and the other is too ready to chalk up symptoms as something the child will "just grow out of," the clinician must navigate carefully to allow both parents to move to a reasonable middle ground that best serves the child's needs. In such instances, understanding each parent's defensive style helps the clinician to avoid appearing to collude with one parent and alienating the other.

Discrepant reporting often results from differences between informants in their willingness or ability to report their views to the clinician. For example, parents or caregivers may be quick to report a behavior that they find disturbing or annoying, whereas a child may be unable to describe the problematic behavior verbally, may not appreciate the level of disturbance that it creates for others, or may minimize or omit it due to feelings of shame or fear of being blamed or punished.

In general, methodologic studies and clinical experience suggest that parents are more likely than children to report disruptive or externalizing child behaviors, such as restlessness, impulsiveness, opposition, or aggression. Conversely, children may be more likely to report anxious or depressive feelings and symptoms, including suicidal thoughts and acts, of which the parents may be unaware. Because children may be immature in their capacity to report information, such as frequency and duration of symptoms, parents are usually more accurate informants about chronologic details. The child or adolescent, however, is often the only source of information on traumatic events, such as sexual abuse, exposure to violence, or behavior that occurred in peer contexts (e.g., bullying). In general, children become more reliable reporters of specific symptoms and time frames with age, with prepubertal children tending to be less reliable reporters of behavioral symptoms than their parents.

Mothers and fathers often differ in their experiences with their children, depending on the nature of their caregiving roles, the child's age and gender, shared interests, and the respective temperaments and personalities of the parents and child. Although mothers have been reported to be more reliable informants than fathers and traditionally spend more time with their children, it is important to gather information from all adult caregivers and to involve and form an alliance with both parents from the outset. When appropriate, other informants, such as siblings, grandparents, or childcare providers, may be called on to contribute information, but only after the implications for the family system and the child's specific relationships with household members are carefully thought out.

Parents and teachers may view the nature and severity of the child's difficulties differently because of the situation-specific nature of some behaviors and symptoms. When present at home and school, symptoms such as hyperactivity and inattention may carry a different clinical significance and prognosis than those noted in only one of the settings. Parents and teachers may also differ in their appraisals of the child's behaviors. For example, a stressed and preoccupied parent or caregiver may be less attentive to her child's behavior, whereas an observant teacher with years of experience with similar-aged children may readily identify the child as distressed, inattentive, or disruptive.

For the clinician conducting the assessment, the issue is not which informant is right but how to understand the differences in viewpoint most effectively for the patient's benefit. Thus, the clinician must elicit and then synthesize the information about the child's behavior and feelings in multiple settings, like school, home, on sports teams, and with peers, in order to provide an optimal clinical evaluation.

INTERVIEW TECHNIQUES WITH PARENTS. The clinician may need to use a variety of interview techniques to elicit information from parents. The type and quality of information obtained are, in part, determined by the methods used and the clinician's skill and comfort in using them. A series of empirical studies confirm that systematic factual information and details about onset and timing of symptoms are generally most easily elicited by specific and direct questions, whereas an understanding of feelings and relationships in the family is usually gained most effectively by means of more open-ended, indirect questioning strategies.

In the initial interview, parents should have the opportunity to tell their story in their own way. For rapport to develop, they must feel that they have been able to express their concerns in their own words and were heard and empathically understood. An open-ended beginning also avoids narrowing down too quickly on a single aspect of the child's situation and conveys the clinician's interest in many different aspects of the child's situation. Subsequent probing can clarify details and help shape the clinician's understanding of diagnostic and potential treatment issues.

Parents are most likely to be nondefensive and comfortable about sharing personal information when they feel that the clinician is trustworthy, interested, understanding, and nonjudgmental. Clinicians must thus convey respect and empathy and avoid seeming either aloof or excessively familiar. They should discuss the child and family's situation in a natural way, using words and concepts that the parents can understand. The range of questions and the tone of the inquiry convey the clinician's interest in the whole child (including strengths, interests, and talents) and an appreciation that the child is not merely the bearer or repository of a set of symptoms.

EXPECTATIONS AND ANXIETIES. Parents may hold strong preconceived ideas about the nature of their child's problem and the kind of help needed. Because of the extensive coverage of issues relating to psychotropic medications in the popular press, many parents have drawn conclusions about the appropriateness of medications in general and in relation to their child's needs. For example, parents may arrive convinced that their child needs fluoxetine (Prozac) or that methylphenidate (Ritalin) is an addicting and inherently harmful drug.

Preconceptions or parental anxiety or conflict may also be played out around the issue of blame for the child's problems. In such situations, a parent may maneuver to have the clinician arbitrate or agree that the teacher, school, or other parent is responsible for the child's behavior and distress. The clinician should be alert to such situations and should handle them without making either parent feel defensive or discounted. If ignored, such hidden or overt agendas can have a deleterious effect on the assessment process and the likelihood that treatment recommendations will be accepted or successfully implemented.

Parents may bring other entrenched, preconceived agendas to the clinical evaluation process. A parent may insist that the evaluation confirm that the child has been abused (e.g., by a former spouse) or does not have a psychiatric problem but a medical one. Alternatively, the parent may demand that the clinician agree that there is nothing wrong with the child. In such instances, clinicians must explain carefully and clearly that they will conduct a thorough assessment and provide thoughtful professional advice, adding that the assessment must be done openly, without preordained conclusions. This may not satisfy some parents, and some situations may simply not be workable.

Bringing a child for psychiatric evaluation is a charged and emotionally difficult step for nearly all parents, and often it is only taken after much worry and disappointment that various accommodations, home remedies, or school-based adjustments have not sufficed. Children are the repositories of parents' dearest hopes (and often darkest fears) for themselves. Although a parent may rationally conclude that seeking consultation is reasonable and necessary, admitting that one's child or oneself needs help is often painful. Submitting one's child and one's parenting to professional scrutiny stirs many anxieties, as well as positive expectations of help, in most parents.

Parents often bring unspoken anxieties about the child's possible diagnosis or prognosis to the evaluation. These anxieties may be based on the parent's personal or family experience with psychiatric disturbance or may derive from accounts in the popular media. For example, is the child's uneven development a sign of autism or intellectual deficiency? Do the facial grimaces mean that the child is developing a disabling tic disorder? Is the child's moodiness a harbinger of a serious mood disorder or suicide? Other parental anxieties may be guilty ones. Is failed parental rearing or transmitted heredity somehow to blame for the child's difficulties? Is the child fated to share the parent's (or other relative's) painful struggle with depression, anxiety, or psychosis? Does the parent's relationship to the child seem to recapitulate some distressing aspect of the parent's own early family experience?

The clinician must be aware of such parental anxieties and thus remain alert for hints of them as the evaluation progresses; some parents are too anxious or ashamed to be forthcoming about them. By and large, it is best to have these concerns aired, even if they cannot be settled at the initial stage of evaluation and perhaps cannot be settled for some time. When such anxieties are revealed or suggested indirectly, the clinician must express an interest in them with sensitivity. Respect and concern for these anxieties can be conveyed without dismissing them or providing premature or unfounded reassurance. The clinician may need to acknowledge the limits of knowledge about cause or prognosis in individual cases. Parents often seek psychiatric assessment after years of worry, having been given well-meaning (but inappropriate) reassurances that the child would grow out of it. Frank discussion of these issues may provide some relief to the parents, albeit perhaps not definitive answers to their questions.

PREPARATION OF THE CHILD. If the child or adolescent does not attend the initial interview, the clinician and parents should discuss the preparation of the child for their first appointment. Children have many reactions to a first visit to the psychiatric clinician, and parents must anticipate their child’s possible reaction and prepare their response. Children may feel anxious because they cannot envision what will occur or because the evaluation may feel like a punishment. Some children fear that the assessment will reveal some profound or irremediable problem (this may be projected onto the clinician or parent with the reproach, “You think I’m crazy”). Many younger children fear shots or having to get undressed for a physical examination. In most cases, the child is probably aware of many of the parental or school concerns that have led to the evaluation and may feel a sense of relief (which can nevertheless coexist with anxiety) about the possibility of getting some help. The child’s anxiety or defensiveness may be reduced if the purpose of the visit is put in supportive (rather than pejorative or accusatory) terms. The parents might be encouraged to tell the child something like, “We know you’ve been having a hard time at school [or feeling upset and sad or having trouble with friends], so we are going to see Dr.—, who is used to helping kids with that sort of problem and can maybe figure out what would help you.” For younger children, explanatory terms, such as a *feelings doctor* or a *talking doctor* who helps children with problems and worries, may be useful. The parents must give permission and encourage children to tell the clinician about their concerns, even those that might seem to involve private family matters not otherwise spoken about to others.

Child Interview

In the child interview, the clinician directly assesses the child’s psychological functioning, developmental status across different domains, and perceptions and experiences of the presenting problems. Consideration of the child’s age and development is critical for the clinician to approach the child in a child-centered manner. Like the parent interview, the child interview also provides an important opportunity to establish rapport. Such rapport reduces the level of stress experienced by the child during the assessment process, enhances the child’s engagement and willingness to share information, and facilitates the child’s cooperation with subsequent recommendations for intervention. Thus, from the outset, the clinician should convey empathy and interest in understanding and helping the child.

There has been debate regarding the reliability, validity, and clinical usefulness of various approaches to the child interview, but it is generally agreed that the direct child interview is an essential component of a comprehensive clinical child assessment. It provides observational data and diagnostic and historical information that are not accessible from other sources. In particular, information about feelings and moods, level of distress, and the child’s view of significant events is essential for a full diagnostic understanding of the child’s problems. For their own reasons, parents may not understand or fully appreciate the importance of these issues, or the child or adolescent may not have divulged them. The child may be guarding important information, such as secrets about abuse, bullying, sexual or antisocial activities, substance use, suicide attempts, pathologic patterns of eating, or collusive family dynamics. Certain symptoms or forms of distress, such as hallucinations, compulsions, premonitory tic urges, obsessive or suicidal thoughts, or concerns over sexual orientation or gender identity, may be apparent only to the child. Other symptoms may escape or mislead the untrained eye; detection of tics or a thought disorder may require direct clinical observation.

There are many varieties of child interviews, depending on the nature of the presenting problem, the clinical setting, and the purpose of the assessment. Thus, the scope, focus, duration, setting, and predominant techniques used vary, depending on, for example, whether the assessment is an emergency department evaluation of a suicidal threat, a pediatric ward consultation of a regressed or uncooperative child, a forensic custody evaluation, an investigation of alleged child abuse, or the evaluation of a child who is academically underachieving, anxious, or manifesting tics.

The clinician approaches the child interview with a developmentally based understanding of child and adolescent functioning and psychopathology. Within this framework, the clinician expects to obtain information relevant to the diagnostic questions raised by the presenting problems and so systematically reviews the major domains of symptomatology. The order and manner of conducting the child interview vary with the child’s age and developmental status, the nature of the presenting problems, the setting and context, and the clinician’s style. The constant elements in the interview process are the orienting framework chosen and the clinician’s clinical skill in engaging and eliciting relevant data from children of varying ages and capacities with diverse problems and concerns. Some data may emerge spontaneously; some require questioning or other deliberate means of eliciting information.

Components of the Child Interview. The components of the child interview are often conceptualized under two broad headings: History taking and the mental status examination. *History taking* involves inquiry into the significant areas of the child’s life and functioning, past and present, including the presenting problem. The *mental status examination* consists of an assessment and description of the child’s appearance and functioning as manifested in the interview. Although these aspects of the child interview can be conceptually distinguished, they usually proceed concurrently. For example, the interviewer may ask a specific question, such as who lives at home with the child or how the child gets along with a sibling or a teacher. From a history-taking point of view, the child’s response provides some information about these facts, as well as how the child feels about them. Although the child’s response is thus of interest for the historical information it reveals, the child is also providing the clinician with data relevant to the mental status examination (e.g., how the child conceptualizes the response, how verbally fluent the child is, how readily the child engages, how confiding or suspicious the child is toward the interviewer). Similarly, while engaging a young child in play with figures or puppets, the clinician can simultaneously gather information for the mental status examination (e.g., speech, relatedness, and conceptual skills) and inferential data about the child’s feelings, fantasies, and conflicts.

Several distinctive characteristics of clinical work with children bear on the manner of conducting the child interview and mental status examination and on interpreting the data that they yield. The focus of history taking and the mental status examination of the child is developmental, that is, it seeks to describe the child's current presentation in various domains and to compare the child's functioning in these areas with that expected for the child's age and phase of development. Another distinctive aspect of the child interview involves the child's potential lability and propensity to react in more immature ways when tired, sick, anxious, or stressed by an unfamiliar situation. Although one can sometimes gather sufficient information for an assessment from a single interview, usually more than one interview is needed to assess the child's optimal or characteristic level of functioning.

Mental Status Examination. For the mental status examination, the clinician observes and assesses the following areas:

Physical appearance: Includes physical development, presence of minor congenital anomalies, style of hair and dress, cleanliness, and other indicators of the quality of self-care or parental attentiveness (or its lack) to the child's physical appearance and hygiene.

Manner of relating to examiner and parents: Includes ease of separation, how confiding or guarded the child seems toward the clinician, eagerness to please or to impress, flirtatious behavior, readiness to make excuses or to minimize, passive withholding, or open defiance. The child's behavior toward the examiner is compared to that observed or reported toward the parents or other adults. Reactions to the clinician's physical appearance, gender, or ethnicity (especially if different from that of the child) should be noted.

Affect: The child's predominant mood and range of emotion during the interview and appropriateness of mood.

Coping mechanisms: As manifested toward the clinician, expressed in play, or described by the child in relation to important others; age-appropriateness of the child's dependent longings, sexual interests and impulses, and aggressive feelings, with respect to intensity, object, and mode of expression; child's control or modulation of such urges (e.g., finding alternative or socially permissible means of satisfying them); strategies used for coping when anxious or frustrated.

Orientation to time, place, and person: Whether children are accurately aware of the date, where they are, and who they are. This can be evaluated by asking the child, "What is the year? season? date? day? month?" or "Where are we?" (name(s) of building, town, state, country).

Motor behavior, including activity level: Coordination, presence of unusual postures or motor patterns (e.g., tics, compulsions, or stereotypies, such as hand flapping or twirling).

Quality of thinking and perception: Includes presence of hallucinations, delusions, thought disorder, flight of ideas, and adequacy of hearing and vision.

Speech and language: Includes reading and writing; articulation, inflection, pitch, rhythm, and fluency of the child's speech; richness, limitation, or idiosyncratic aspects of vocabulary and syntax; presence of echolalia or persistent neologisms; misuse of pronouns and gender; delayed or deviant social use of language; and lack of accompanying nonverbal communicative behavior (e.g., lack of facial expression or eye contact with interlocutor). When evidence of delays or problems in these realms exists, formal speech and language evaluation by a qualified specialist may be warranted.

Overall intelligence and fund of knowledge: Capacity for classification, abstraction, and inference appropriate to age; counting, alphabet, days of the week, months of the year, reading, writing, computational abilities; geographical and historical facts.

Attention, concentration, and impulsivity: Level of attention to an activity or topic of discussion, degree to which child jumps from activity to activity, need for physical limits, distractibility (e.g., by outside noises).

Memory: Immediate short- and long-term memory (e.g., repeat three items and recall at 5 and 30 minutes).

Neurologic functioning: Fluctuating alertness, tremor, nystagmus, choreiform movements, abnormal gait, and cerebral dominance (preferred hand, foot, eye, or ear); testing for neurologic soft signs can be incorporated in a game-like fashion (e.g., ball throwing, walking on a line, heel-to-toe walking, evidence of hand overflow when walking on outside of feet, repetitive or sequential finger tapping, and alternating pronation–supination of the hand are relatively reliable components of a standardized exam for neurologic soft signs).

Judgment and insight: Especially concerning the presenting problem; this is most usefully judged after the child has had the opportunity to develop some rapport with the clinician because the child's initial impulse may be to deny or to minimize the parents' presenting concerns.

Preferred modes of communication: Is the child open to talking directly about the presenting problems and the significant aspects of their life, or is the child more comfortable with indirect modes of expression, such as play or drawing?

Reliable detailed assessment of a child's speech and language capacities, intelligence, academic attainment, attentional and executive functioning, and memory requires standardized psychometric testing. Some simple tasks, such as those used in the Mini-Mental State Examination (as adapted for children by R. A. Ouvrier and colleagues), can be incorporated in a game-like fashion into the interview of the child to provide a rough screen of higher mental functions, such as orientation, attention, memory, language, and constructional ability.

Although the clinician should usually evaluate all areas of the mental status assessment, the emphasis and detail given to the different elements vary with the presenting problem and the type of assessment. For example, in an agitated, potentially delirious child on a pediatric ward, particular attention is paid to the child's orientation, alertness, memory, verbal coherence, neurologic functioning, and the possible presence of hallucinations.

Child Interview Techniques. A range of techniques is used in the psychiatric interview of the child or adolescent. The choice and timing of techniques depend on the child's developmental, cognitive, and linguistic level; the emotional difficulty of the issue being addressed; and the degree of rapport between child and clinician. Being able to gauge the potential usefulness of a technique at a particular moment and feeling comfortable with shifting from one technique to another as the occasion demands are important acquired skills for those conducting child and adolescent clinical assessments.

PLAY TECHNIQUES. Children younger than 8 years of age have less mature capacities to recount their feelings or interpersonal interactions verbally. For these younger children, as well as many older ones, play is a useful adjunct to direct questioning and discussion and is often a less challenging mode for the child. Some children find it easier to communicate in displacement; thus, imaginative play with puppets, small figures, and the like, either solo or in interaction with the interviewer, can provide useful inferential material about the child's concerns, perceptions, and characteristic modes of regulating affects and impulses.

The skilled interviewer can facilitate the child's engagement in play without prematurely introducing speculations or reactions that might distort or cut short the presentation of certain types of material. During the course of play, the clinician follows the sequences of play content, noting themes that emerge, points at which a child backs away from the storyline or shifts to a new sequence or activity, and situations in which the child gets stuck or falls into a repetitive loop. To facilitate the play component of an interview, the interview room should have a supply of human and animal figures or dolls and appropriate props. These should be relatively simple because elaborate toys can become distractions rather than serve as vehicles for the expression of the child's fantasies. Stock figures (such as Barbies, superheroes, or Disney characters) may impose specific storylines and themes and thus may limit access to the child's own concerns.

Not only is the content of the child's play a rich source of information, but careful observation of the form of play also provides important information for the mental status examination. During imaginative play, the clinician can observe the child's coordination and motor capacities, speech and language development, attention span, readiness to engage the interviewer, capacity for complex thought, and affective state. Absence of imaginative play or very limited, concrete, noninteractive play may indicate an autism spectrum disorder.

Games, such as cards or board games, are also useful for putting the child at ease and developing rapport. These provide opportunities to observe the degree of the child's engagement in and enjoyment of the shared activity; how the child manages competition, including reactions to winning or losing; or whether the child is prone to cheating. Some play activities (e.g., throwing a ball back and forth or easy card games, such as War) are simple enough to permit ongoing conversation while helping to discharge tension and diminish the pressures of the interview situation. As with toys, elaborate games (e.g., chess) should be avoided; games that demand much cognitive energy and concentration usually preclude discussion of issues relevant to the assessment and lend themselves to avoiding issues involved with the child's difficulties.

PROJECTIVE TECHNIQUES. In addition to imaginative play, projective techniques often help provide an indirect picture of concerns that the child may be reluctant or unable to report directly. These techniques can help the child to feel more comfortable with the clinician, are often experienced as fun, and may provide access to concerns that are important to the diagnostic formulation.

One commonly used technique is picture drawing. The child can be asked to draw a picture, leaving the choice of subject up to the child or, alternatively, can be given a specific request (e.g., to draw a person or the child's family doing something). When the picture is finished, or nearly so, it is helpful to compliment the child's effort and to express interest in what is happening in the drawing. The child's elaboration provides information that may not be readily apparent from the drawing itself. The content and form of the drawing offer a window on the child's emotional concerns and aspects of intellectual and visuomotor development. For example, the relative size and placement or omission of family members in a family drawing may be important nonverbal indicators of the child's perceptions or feelings about the family. Aggressive or sexual themes may be reflected more readily in drawings than in words. Self-image may be indicated through depictions of the child as grotesque, inconsequential, superhumanly invulnerable, or different than the child's birth gender. The clinician should become familiar with the developmental progression and norms for human figure details, such as limbs, joints, facial features, and clothing, which can provide a useful rough estimate of intellectual maturity. Various systems have been developed for systematically assessing the cognitive and emotional aspects of children's drawings. In addition, the child's behavior and speech while drawing may yield useful information (e.g., throwing the picture away unfinished and saying that it is no good).

Frequently used verbal projective techniques include asking what animal the child would most or least like to be or whom the child would pick to take along to a deserted island. It is useful to ask what the child would do with three magic wishes; if elaboration is needed, the clinician can explain that the wishes could be to have anything, to have the world be different in any way, or to change oneself in any way. Children's responses are often revealing. Some may needily or impulsively wish for material possessions, such as a video game or a billion dollars. Other responses may reveal longings to change distressing circumstances, such as “for my mom and dad to get back together again,” “not to have tics anymore or to get teased about them,” or “to have a dad who doesn't yell at me all the time.” Still other children appear uncomfortable wishing for something for themselves, preferring instead seemingly altruistic responses, such as “no more poverty or wars.” Children's responses can be used as the starting point for further exploration. For example, the child who wishes for “a big house and lots of money” may be asked who else would live there and what they would do together. Children who wish for “no more fighting in the world” can be asked if there are some particular fights that they would especially like to stop.

Some interactive imaginative techniques useful to interviewers comfortable with them provide elements of playing a game, which may appeal to the child. The squiggle drawing game developed by Donald Winnicott consists of the clinician drawing a curvy line and asking the child to turn it into a picture of something; the child then draws a curvy line that the therapist elaborates, and so on, taking turns. The Despert Fables are a series of incomplete, affectively evocative stories that the child is asked to complete.

Asking the child to tell about a dream or a book, movie, or television program can provide information about the child’s interests and preoccupations. (If the clinician is familiar with the plot, the distortions the child may introduce can be informative regarding the child’s cognitive and emotional style.) Inquiring about what the child would like to do for a living when grown up can provide insight into the child’s aspirations, values, and concerns, as well as those of the family.

DIRECT QUESTIONING. Direct questioning about the current problems and other aspects of the child’s life requires tact, attention to the child’s level of cognitive and linguistic development, and regard for the effect of the questions on the child’s self-esteem. The goal of such discussion is to determine how children see their world and their functioning in it, including attachments and antipathies, pleasures and anxieties, and strengths and weaknesses, which may include the difficulties that led to the evaluation.

It is important to phrase questions in language that is appropriate to the child’s developmental level and verbal capacities. Children may become confused or made more anxious by technical words or abstract or complicated questions. Closed questions often yield little information. For example, “Do you get along OK with your brother?” may bring forth a simple “yes” or “no,” whereas open-ended or descriptive questions are more likely to elicit a richer picture of how a child thinks and feels (e.g., “What sort of guy is your brother?” or “Tell me about your last play-date with Danny.”). Some usefully evocative questions include “What sorts of things make you mad (or make you feel afraid)?” “What is your saddest (or happiest) memory?” “What do you like to daydream about?” If it is important to establish the order or duration of events, school-aged children do better if the questions are anchored to markers in their lives (e.g., “Did that happen before or after your birthday?” or “Have you had trouble with that since school got out?”). Several empirical studies by Michael Rutter and colleagues have examined the effects of various interview styles on the information elicited from children and parents.

Although direct questions are often needed to initiate or to focus discussion, settling into a direct question format may constrict the interview process and give children the impression that the clinician just wants to hear facts or chronology and is not so interested in the child’s feelings and experiences. Young children frequently respond in a manner that they believe to be socially desirable, whereas older children are often reluctant to acknowledge feelings of sadness or vulnerability, even to themselves. Clinicians should convey, by demeanor and tone of voice, their interest in the child’s real feelings.

When discussion of feelings seems difficult for the child, it may be useful for the clinician to acknowledge the link between a situation and the child’s affective response (“Some kids might have felt mad if that happened to them; how about you?”). However, the clinician must avoid leading a child whom the clinician does not yet know well by assuming experiences or feelings. Probing a bland, equivocal response may prove useful; for example, in response to “Okay, I guess,” the clinician may say, “Sounds like you’re not quite sure.”

The assessment should convey respect for the child and should protect the child’s self-esteem. Many children feel ashamed or guilty about the difficulties that have brought them to the evaluation. When the clinician conveys a nonjudgmental understanding, using language that suggests that the difficulties are problems to be helped rather than transgressions, the child is more likely to be forthcoming. The child has come to the evaluation because of problems, but one should also talk with the child about strengths. For example, in inquiring about school, it may be useful to say, “Tell me about the parts of school you like best" before asking, "Are there subjects [classmates, teachers] that give you trouble?" or "What are the rough spots at school?" It may be better to ask the socially isolated child, "Do you sometimes have trouble making or keeping friends as much as you'd like?" and then "What do you think the trouble is?" rather than "Do you have any friends?" (especially if the truthful answer to this question is "no").

Structure and Sequence of the Child Interview. When interviewing the child, the clinician has in mind an overall map of the functional and historical areas to be covered; however, the format and sequence of any given interview are responsive to the individual child, the presenting problems, the unfolding pattern of the interview, and the clinician's personal style. For example, in every assessment, the clinician should ask about the cardinal symptoms of depression, anxiety, and disruptive behavior disorders, but when, how, and in what order this is done vary from one interview to another.

BEGINNING THE INTERVIEW. There are various ways to start the interview. The one chosen should be comfortable for clinician and child and should set the stage for a productive interchange. Many clinicians prefer not to address the presenting problem(s) immediately at the outset. Some clinicians, for example, remain quiet and let the child look about the room and begin playing or talking without prompting or guidance. This approach imposes a minimum amount of structure; the clinician can see how the child reacts to the materials present in the playroom and to the clinician. It also provides information about how the child handles the situational anxiety that is often evoked by the first meeting with the clinician. However, this unstructured approach may leave many children disoriented and uncomfortably uncertain as to the clinician's goals and intentions. Other clinicians are more direct in attempting to place the child at ease and begin by inviting the child to explore the available play materials ("What looks interesting?"). Others open the interview by inquiring about neutral or pleasurable topics ("Tell me about what you like to do for fun."). The clinician must read the child's cues regarding level of comfort and urgency in deciding when to address the problems that led to the evaluation. Some children prefer to first talk about nonthreatening topics, whereas others expect to get down to business and talk about their problems right away.

Although it may be useful to establish some initial rapport around neutral or interesting topics, most children understand that they have not come for a conventional social encounter. Hence, relatively early in the interview, it is useful to ask what the child's ideas are about the purpose of the meeting. It is usually best to do this in a matter-of-fact manner by asking, "What did your mom and dad tell you [or what do you know] about why they wanted you to come and see me today?" If the child has already met with the clinician together with the parents as part of an earlier contact, the clinician will have asked something similar at that time and may have heard about the child's view of the presenting problem and its history. If so, the clinician can follow up by saying, "Last time, mostly your mom and dad said what they thought about things. Today, we have a chance to talk more about how things look to you. Are there any things we talked about then that we should talk about today?" Asking what the child knows or thinks about the purpose of the evaluation shows the clinician's interest in the child's view of the situation and allows the clinician to hear how the child describes or assumes responsibility for the problem (or repudiates it as someone else's concern). Asking for the child's view up front, before the child has become deeply engaged or focused on some aspect of the interview process, allows the clinician to address misapprehensions. It also provides an opportunity for the clinician to explain, in terms that can be understood and potentially acknowledged by the child, the issues (at least as the clinician understands them) that have prompted the assessment.

ASSESSMENT OF MAJOR REALMS OF FUNCTIONING. Throughout the assessment, the clinician elicits and assimilates information to develop a picture of the child's functioning in the realms of family, school, peers, and recreation. Discussion of the presenting problem reveals information, particularly with respect to impairments, in these domains; however, additional discussion of the child's experiences in these areas enhances the picture of the child’s life and level of adaptation. It is often useful to begin exploration of each of these realms by asking for objective facts (e.g., “Who lives at home with you?” “Whom do you like to play with [or hang out with]?” “What school do you go to? What grade are you in?” or “What do you like to do for fun?”). This can be followed up with probes for more subjective views: “How do people in your family get along? Are there any problems at home? Things people fight about? Things you get in trouble for? Things people at home do that you don’t like?” This approach is intended to open up discussion of the major realms of functioning, not simply to elicit rote responses.

It is often helpful to begin by inquiring about the child’s recreational activities (“What do you like to do for fun?”). This allows the clinician to learn about the child’s interests, preoccupations, and talents and may provide a less threatening or problematic starting point than the areas of peer and academic functioning. Family functioning can be approached by asking who lives at home, how the child gets along with each person, and how family members get along with each other. One can also inquire more specifically, “What do you like to do with your dad [or other relative]?” or “What is your brother like?” In the case of nontraditional family structures or families of divorce or separation, the clinician may inquire about the history of the current arrangement and what sort of relationship is maintained with the noncustodial parent(s).

INQUIRY ABOUT PSYCHIATRIC SYMPTOMS. Just as a medical evaluation includes a review of key symptoms in the major systems, the child psychiatric evaluation should include a set of questions that screens for symptoms of common or major psychiatric disorders. The family or child may not see a link between one behavior or area of distress and another and may not volunteer symptoms that seem unrelated to the presenting problem. Comorbidity is relatively common in children with psychiatric disorders. Thus, the child psychiatric clinician must routinely question across the major areas of psychiatric disorders. Using developmentally appropriate language, this inquiry should cover depressive symptoms (e.g., low self-esteem, anhedonia, and suicidal ideation or behavior), self-harm (e.g., cutting), excessive anxiety or fears, obsessions and compulsions, hallucinations and delusions, and antisocial behaviors. For example, one should ask, “Do you feel sad or grumpy a lot of the time? Do you often feel like crying?” If the answer is positive, one can follow up concerning persistence (“Does that last for more than a few minutes?”), frequency (“Does that usually happen every week [or most days]?”), and context (“What sorts of things make you feel that way?”). To inquire about suicidal ideation, one can begin by asking, “Do you ever feel that life is so hard, you wish you weren’t alive [or would be better off dead]?” following up with the more explicit “Have you ever tried to hurt yourself [or done anything to try to make yourself dead]?” Exposure to potentially traumatic experiences should be routinely covered, and developmentally appropriate language should be used (e.g., “Have any really scary things ever happened to you?” “Has anyone ever touched you in a way that made you uncomfortable?”). The child should also be given an open-ended opportunity to talk about concerns that have not been specifically queried or anticipated by the interviewer. (“Are there any other worries that you have or things that make you unhappy that we haven’t talked about yet?”)

MENTAL STATUS EXAMINATION. Throughout the clinical interview, the clinician observes and notes information relevant to the domains of the mental status examination. Some abnormalities or deficits may be evident through this process; however, other areas require direct examination, which can usually be incorporated in a playful way into the clinical interview. Although intensive developmental, psychometric, language, and neurologic assessment usually cannot be subsumed within the clinical interview, a brief semi-structured evaluation requires only approximately 5 to 10 minutes and provides useful information. This generally involves drawing, copying a design, and engaging in simple tests of orientation, recall, general knowledge, and language (e.g., naming three objects; repeating a phrase such as “No ifs, ands, or buts”; a three-stage command, such as “Take a piece of paper in your right hand, fold the paper in half, put the paper on the floor”; a writing sample [such as asking the child to write a sentence of their choice]; and a brief screen of neurologic soft signs).

CLOSING THE INTERVIEW. In winding up the interview, the clinician can check for concerns that have not been covered and that also signal that the interview is coming to a close by asking, “We’ve talked about a lot of things; are there any other things that would be important for me to know about you?” Similarly, one might ask, “I’ve asked you a lot of questions; do you have any questions you want to ask me?” The clinician should also give the child a general idea of what will be done with all the information the child has shared and some sense of what happens next. For example, one might explain, “I’m going to think over what I’ve heard from you and your folks and meet again with them (and you) to talk about what might help with—. Are there any particular things I should be sure to mention?” If the clinician already has a sense of what interventions might be helpful, this may be tentatively broached with the child, keeping in mind the parents’ right to hear and decide on those recommendations.

Clinician and System Factors

In the past decade, there has been an increased awareness of the potentially distorting effects of implicit biases in the clinician as well as systemic cultural and racial issues that can impact the child and adolescent mental health treatment system. These range from implicit (or explicit) biases in the individual clinician and extend to cultural, socio-economic, and racial issues that may impact the family’s encounter with the clinic setting. It is important for clinicians to educate themselves and become aware of their own potential biases in order to be cognizant of how and when these biases might affect how they view their patients and their families. Systemic biases in how seemingly “objective” diagnostic criteria or psychometric norms are applied can influence the diagnoses assigned children from racial or ethnic minorities. The article “The Essence of Innocence: Consequences of Dehumanizing Black Children,” by Goff and colleagues (2014), identified the following example of implicit racial bias: black male youth are often assumed to be older than their chronologic age so that typical adolescent behaviors are often viewed as more menacing or potentially dangerous than they should. These types of biases, in conjunction with disparities in access to mental health services, contribute to the striking differences between groups in assigned treatments and outcomes.

SPECIAL ISSUES IN THE ASSESSMENT OF ADOLESCENTS

The clinical assessment of adolescents requires familiarity with the distinctive dynamics of adolescents and their characteristic patterns of managing conflicts, anxiety, and interactions with adults.

The adolescent's attitude toward the evaluation has important implications for how the assessment process unfolds. In contrast to the adult patient (who usually takes some responsibility and initiative in seeking help) and the child patient (who is simply brought by parents), many adolescents are cautiously ambiguous as to whether there is a problem with which they want help or whether they are merely passively (or reluctantly) complying with their parents' initiative.

One important initial decision involves who is to be seen in the initial interview: the parents, the adolescent, or all together. Seeing adolescents alone first has the advantage of emphasizing their active participation in the process and underlines the clinician's interest in their perspective; however, it may mean that crucial elements of the history are not available to the assessor. The clinician may opt to divide the initial interview into an allotment of time for the adolescent alone, the parents alone, and all of them together. Some adolescents may protest that they are being singled out as the identified patient or bearer of a problem that they feel resides in their parents or in the family as a whole. The clinician may need to explain explicitly to the entire family that the evaluation is not a judicial proceeding to assess blame but rather an attempt to understand what the problems are.

In some cases, when the adolescent balks at being seen at all, the clinician may need to meet with the parents alone to facilitate the youngster's participation in the evaluation. Regardless of when the adolescent is seen, the parents should, at some point, be seen alone to explain their concerns about the child, to obtain a full developmental and family history, and to hear about aspects of their spousal and parenting relationship that may be clinically significant but that may not be appropriate to discuss initially in the adolescent's presence.

Meeting with the adolescent and parents together is usually helpful. This provides an opportunity to explore how family members interact, their convergences or divergences of perspective, and their capacity to work together therapeutically. Such conjoint interviews usually require active structuring by the clinician, so that the purpose is framed as an occasion to talk together. Without such active intervention, the family session can easily deteriorate into an adversarial proceeding in which the parents complain about the adolescent, who, in turn, retreats into hostile or guarded silence.

Confidentiality

The assessment of adolescents often raises complex issues of confidentiality. Although the parents and the adolescent must know that the adolescent's communications are kept confidential, they must all understand from the onset that this does not extend to situations that pose a clear danger to the patient or others. For example, if the adolescent reveals significant suicidal ideation or a recent suicide attempt of which the parents are unaware, parents must be informed for the youngster's safety. Having made clear that the parents need to know, the task is then to negotiate whether the adolescent prefers to tell the parents directly or to have the clinician inform them. It is usually best to have the adolescent undertake this responsibility, but sometimes, after discussion with the youngster, the clinician must be the one to speak with the parents, preferably in the adolescent's presence. Less clear-cut situations in which the adolescent reveals problematic but not imminently dangerous antisocial or sexual behavior or substance use must be decided on an individual basis. Treatment may not be possible without some confidentiality; however, confidentiality must not become collusion.

Developmental Issues

Adolescents' developmentally appropriate push toward autonomy is often linked to a wariness about feeling vulnerable, dependent, or controlled. Tolerating feelings of ambivalence, guilt, or other painful affects or internal conflicts does not come easily to adolescents. In addition, adolescents are prone to externalize their concern or embarrassment over self-perceived shortcomings or difficulties. As a result, even adolescents who consciously desire help often approach a clinical assessment with the fear that revealing what they perceive as shameful weaknesses leaves them vulnerable to criticism, control, or regressive dependency. Fear of acknowledging vulnerability or dependency may result in bland denials of any problems or insistence that "I can handle it by myself" or "I don't need a shrink; I can talk about my problems with my friends." Externalizing their conflicted feelings about autonomy versus dependence, adolescents may fluctuate between grievances about parental overprotectiveness and complaints about perceived lack of care. Adolescents who adamantly reject the notion that they are experiencing difficulties or need help may be masking anxiety, shame, or other painful feelings of vulnerability. The skilled clinician learns to look beyond surface behavior and to notice when an adolescent "doth protest too much."

Although many adolescents seem intolerant of self-reflection, an unrealistic belief in the omnipotence of thought often helps to support denial and avoidance. Even when confronted with a pattern of long-standing maladaptive behaviors, the adolescent may insist, "I can stop any time I really want to," or "I don't do that anymore" (i.e., not since Saturday).

The lability of adolescents' moods and their truncated time perspective often make it useful to extend the evaluation over time to distinguish the transient issues from those that are more enduring.

Technical Issues in the Adolescent Interview

Interviewing adolescents requires tact, flexibility, a sense of humor, and clinicians who have come to terms with their own adolescent issues. Condescension, sarcasm, competitiveness, or excessive passivity on the part of the interviewer is likely to result in failure. However, although conveying a genuine interest in the youngster is essential, seductiveness, overfamiliarity, or the failure to maintain an adult role is likely to frighten the adolescent. The interviewer should resist the temptation to be too “with it” or too “cool”—nothing is more dated than last year’s slang. Because adolescents can so easily feel defensive, criticized, or embarrassed, the interviewer must learn to talk frankly yet tactfully about areas of apparent difficulty. Many embattled adolescents see adults as either for them or against them. Hence, the clinician needs to convey a genuine empathic interest in the adolescent’s view of a situation without implying collusive, uncritical acceptance of it or entering into an adversarial dispute.

The general observation that it is important to learn about youngsters’ strengths and interests, as well as their problems and vulnerabilities, is especially true of adolescents. Without appearing squeamish or avoidant of the problem areas, the clinician should inquire about the adolescent’s interests, hobbies, recreations, and friendships. Knowledge about the areas of accomplishment, talent, and gratification is required for a full picture that includes the youngster’s adaptive and compensatory strengths and assets. Furthermore, such an inquiry helps to facilitate rapport and conveys an interest in the adolescent as a whole person rather than simply as a bearer of problems. A too-exclusive focus on pathology puts many youngsters on the defensive, and an opportunity to talk about more neutral areas or those of greater mastery or confidence helps the adolescent to feel less on the spot. Instead of the interviewer straining to demonstrate familiarity with the latest band, cool video game, or winning team, letting adolescents teach the interviewer about the details of their interests lets youngsters enjoy a sense of mastery, control, and a degree of parity with the adult interviewer that helps to put them at ease. Indeed, a frequently useful technique in the adolescent interview is what Hilde Bruch called *the constructive use of ignorance* (and others have termed “the Colombo” technique after the eponymous detective’s seemingly guileless interrogatory style). This consists in being able to ask about some missing piece in the story or about some puzzling impasse with an ingenuous curiosity that invites the adolescent’s self-reflection (rather than cross-examining with confrontational or prosecutorial zeal).

Although interviewing and taking the history of the adolescent cover the same general areas outlined previously, certain domains are of particular salience with the adolescent. These relate to the core developmental tasks of adolescence: developing increased autonomy and individuation from parents; taking over the tasks of physical self-care; developing a satisfying, realistic body image in the face of pubertal changes; mastering burgeoning sexual and aggressive impulses; consolidating a social identity, including ethical values and vocational goals; delineating a gender identity; developing a network of satisfying peer relations; and in later adolescence, developing a capacity for romantic intimacy with an appropriate partner (Tables 35.1–1 and 35.1–2).

Table 35.1–1.
Developmental Growth Tasks of Adolescence

1. Gradual development as an independent individual
2. Mental evolution of a satisfying, realistic body image
3. Harnessing of appropriate control and expression of sexual drives
4. Expansion of relationships outside of the home
5. Implementation of a realistic plan to achieve social and economic stability
6. Transition from concrete to abstract conceptualization
7. Integration of a value system applicable to life events

Reprinted with permission of Elsevier from Gross RT, Duke PM. Adolescence. In: Levine MD, Carey WB, Crocker AC, Gross RT, eds. *Developmental Behavioral Pediatrics*. WB Saunders; 1983.

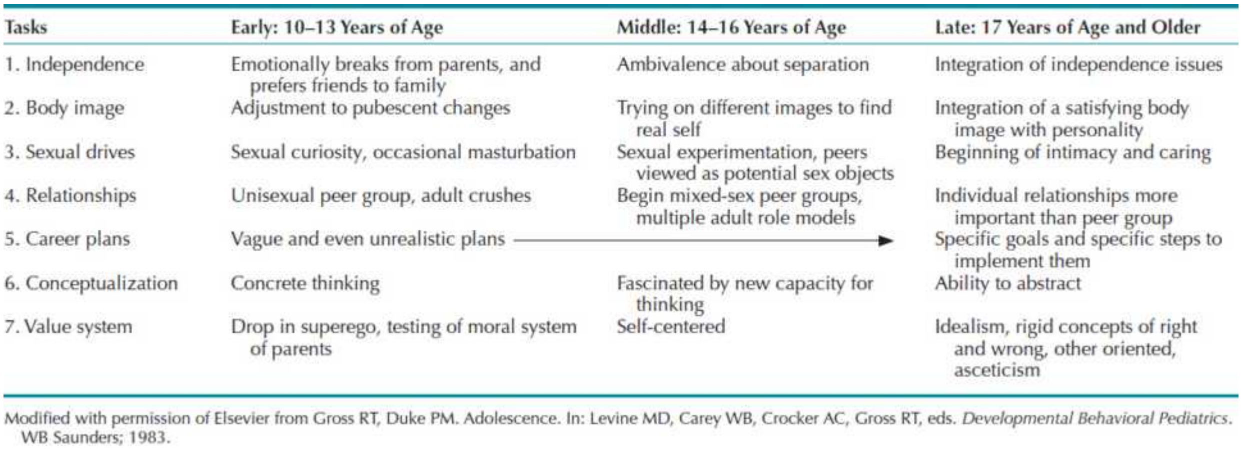
In the realm of values, ideals, and aspirations, the clinician should explore the adolescent’s values and the models whom the adolescent wishes to emulate or to reject. To what extent do these values complement or conflict with those of the parents? What expectations and aspirations (realistic or not) does the adolescent have concerning the future?

The world of peers and friends should also be explored with adolescents. With whom do they hang out? What crowd do they see themselves part of? How do they get along with peers, and what do they do for fun? Asking teenagers to describe a close friend provides a chance to learn how they think about people and relationships and to assess their capacity for empathy.

It is also important to inquire about the adolescent's use of the Internet and social media. How much time does the youngster spend online or on a mobile device? What is the balance of in-person (*IRL* or "in real life") interactions with local flesh-and-blood acquaintances versus purely electronic ones? Has the youngster had any upsetting experiences online, such as cyber-bullying, sexting, or sexual harassment?

The topic of friends leads naturally to the topic of romantic and sexual interests and relationships and gender identity. Exploration of this area requires tact, and the clinician cannot always be sure of receiving a candid response. Nonetheless, as with questions concerning depression or substance use, the clinician's tone can convey the sense that the inquiry into these sensitive areas is motivated by a genuine and legitimate wish to understand the adolescent. One can broach the topic of gender identity by asking "what pronouns do you like to go by" or "how do you like to be called?" If indicated, this can lead to a discussion of whether youngsters view themselves as male, female, or something else. As for sexual orientation, one can begin by asking whether the teenager dates (or "goes out with") anyone and whether there is anyone of either sex with whom the youngster is close. If so, who are they, and what attracted the adolescent to them? Are the adolescent's interests reciprocated? How has the relationship gone? Does the teenager note any recurrent patterns in terms of the type of person to whom they are attracted or how such relationships have unfolded in the past? Have any of the teenager's relationships developed into sexual ones? Has the adolescent had other sexual experiences? (Here one must be open to hearing about possible episodes of sexual abuse or non-consensual sex).

Table 35.1–2.
Growth Tasks of Adolescence by Developmental Phase



Tasks	Early: 10–13 Years of Age	Middle: 14–16 Years of Age	Late: 17 Years of Age and Older
1. Independence	Emotionally breaks from parents, and prefers friends to family	Ambivalence about separation	Integration of independence issues
2. Body image	Adjustment to pubescent changes	Trying on different images to find real self	Integration of a satisfying body image with personality
3. Sexual drives	Sexual curiosity, occasional masturbation	Sexual experimentation, peers viewed as potential sex objects	Beginning of intimacy and caring
4. Relationships	Unisexual peer group, adult crushes	Begin mixed-sex peer groups, multiple adult role models	Individual relationships more important than peer group
5. Career plans	Vague and even unrealistic plans →		Specific goals and specific steps to implement them
6. Conceptualization	Concrete thinking	Fascinated by new capacity for thinking	Ability to abstract
7. Value system	Drop in superego, testing of moral system of parents	Self-centered	Idealism, rigid concepts of right and wrong, other oriented, asceticism

Modified with permission of Elsevier from Gross RT, Duke PM. Adolescence. In: Levine MD, Carey WB, Crocker AC, Gross RT, eds. *Developmental Behavioral Pediatrics*. WB Saunders; 1983.

Because of the high prevalence of depression, self-harm, suicidal ideation, and even suicide attempts in the general population, specific inquiry about these areas as outlined previously is particularly important. The clinician should also inquire matter-of-factly about whether the adolescent smokes, drinks, or uses drugs illicitly, and, if so, with what frequency, in what amounts, in what contexts, and with what consequences.

ASSESSMENT OF INFANTS AND TODDLERS

The assessment of infants and toddlers poses special challenges for the clinician. First, the evaluation of young children requires specific and detailed familiarity with the cognitive, linguistic, motor, and adaptive developmental landmarks from birth to 6 years of age, as well as the specialized techniques needed to assess these competencies. Second, although direct observation of the child is an important source of data, the preverbal or limited verbal capacities of the child severely restrict the historical material that can be obtained from the direct interview of the child. Third (and perhaps most important), infants and young children cannot be assessed, diagnosed, or treated apart from their caregiving environment, which includes not only the parents but also other members of the extended family and other care providers, such as paid and unpaid childcare providers.

The developmental tasks of infancy include achieving physiologic homeostasis; developing stability of state and learning to negotiate transitions between states; organizing basic physiologic rhythms of wakefulness and feeding; coping with novel stimuli; perceiving coherent patterns of experience; mastering simple sensorimotor schema; establishing a specific and secure relationship with a caretaker; maintaining a positive affective tone; developing expressive and receptive channels of communication (including vocalizations and facial and gestural cues); and forming schemas of causality, intentionality, object permanence, and affect. The older infant or toddler must grapple with regulating and socializing bodily functions (e.g., eating, toileting, and sleeping), learning to concentrate and regulate shared attention, acquiring the capacity for imaginative play and more complex forms of imitation, dealing with the challenge of socialization (including development of more complex forms of social perception, communication, and empathy and negotiating conflicts of will with caregivers and peers), and regulating negative and positive mood and aggression. Development can proceed at a different pace in each area and may go awry or be delayed in any or all of them.

The goal of the developmental assessment of infants and toddlers is to depict their functional capacities in each of these areas, the relationships among the various domains of their development, their ability to adapt, and the range of coping strategies that they use in doing so, as well as the caregiving environment as it affects them, the quality of caregiving interactions, and the effect of their developmental status on the caregiver. As with older children, the purpose of the assessment is to define what, if any, interventions are necessary, while at the same time helping to form an alliance with the parents that facilitates implementation of any recommendations that may come out of the assessment. The assessment process itself, properly done, increases parents' sensitivity, awareness, and reflectiveness about their child's development, and in this respect the assessment of an infant or toddler may be an effective parenting intervention, as the parents observe their own child and learn more about his or her capacities and challenges.

The most common referral problems for infants and toddlers involve the following:

1. Developmental delays (e.g., specific delays, such as delayed, absent, or deviant motor or speech development, or general delays in multiple areas of development).
2. Psychophysiological dysregulation (fussy behavior, disturbances of sleep or feeding, rumination, eczema, self-stimulatory behaviors [e.g., head banging, rocking], and failure to thrive).
3. Behavioral disturbances (excessive tantrums, excessive negativism, aggression, and hyperactivity).
4. Disturbed social development (lack of apparent awareness of or interest in others, response to abuse, neglect, or multiple placements or repeated or prolonged separations).
5. Medical or genetic problems that may compromise a child's development (e.g., prematurity and genetic syndromes), exposure to toxins (such as lead or fetal alcohol syndrome).
6. Exposure to environmental stressors (such as maternal depression, change of caretaker, domestic violence or other trauma, reaction to transitions, e.g., beginning preschool or out-of-home childcare, parental marital separation).

The source of these referrals are often pediatricians, clinical social workers, child protection workers, parents and other adult family caregivers, and increasingly extra-familial childcare providers who may have concerns about the child's functioning within a group congregate care setting. The referral also may be prompted by consideration of early intervention services provided by a state agency through Part C of Individuals with Disabilities Education Act (IDEA), the Program for Infants and Toddlers with Disabilities.

Because all aspects of early development are interdependent, the significance of difficulties in one functional domain cannot be understood without reference to the child's developmental status in other areas. For example, speech, language, and hearing difficulties profoundly affect personal and social development. Assessment of motor or adaptive competency that involves interaction with the caregiver or assessor is affected by disturbances in relatedness and hence yields findings that appear erratic or uneven. Infants and toddlers are particularly sensitive to environmental stresses, which may delay the appearance of phase-appropriate skills or may lead to transient regressions.

Technical Issues in the Development of the Infant and Young Child

The assessment of the young child usually requires several brief sessions. In addition to sessions spent with the parents alone to gather history and to present the results of the assessment, familiar adults must be present during the assessment of the child; this is necessary to place the child at ease in the assessor's presence and to permit direct observation of child and caregiver interaction. Furthermore, the behavior of infants and young children is highly state dependent (and sensitive to fatigue or illness), and one usually needs to see the child on more than one occasion to have a sufficient sample of characteristic behavior.

The general principles of history taking from the parents and assessment of the caregiving environment follow those outlined previously. However, particular emphasis is given to the parental perception of the pregnancy with the child—whether the conception was planned or came at a good time in the life of the family and what the effect of the child's arrival was on the parents individually, on older siblings, and on the family as a whole. The history should explore parental (and grandparental) expectations for the child, the meaning that the child has for them, whom the infant reminds them of, what they perceive as the child's best and most challenging traits, any trauma or stressful disruptions of caregiver relationships, and what a typical day in the life of this child is like.

The developmental history for the young child includes prenatal, perinatal, and postnatal complications, including maternal illness, medication and substance use, and neonatal status. In addition to the areas outlined previously, assessment of the child's behavioral organization should include the regulation of physiologic state, alertness, and activity patterns. Children's ability to console themselves and to adapt to new situations and their response to separations are also key areas of evaluation. The history should also include the history of child care arrangements (nannies, relatives, out-of-home child care) and the child's reactions to new care environments or changes in these arrangements. (Many young children spend about as many waking hours in the care of a paid caregiver as they do with their parent(s), hence, in many cases, it may be very useful to hear the report of these extra-familial caretakers who often have a much larger store of observed normative child development to which this child's development may be compared and contrasted.)

The child's mastery of various gross motor, fine motor, language, adaptive, and personal-social milestones should be systematically assessed by history and in the direct evaluation of the child. In taking such a history, the assessor may be aided by a variety of structured or semi-structured caregiver report instruments, such as the Vineland Adaptive Behavior Scales, Third Edition (Vineland-3). It is useful to inquire about the timing of the child's mastery of these milestones relative to those of any siblings; this also helps to gauge parental expectations and to learn more about sibling dynamics. The Vineland-3 provides a semi-structured interview format that can be easily woven into a developmental history.

Within the first few months of life, children begin to manifest distinctive and often enduring behavioral styles or temperament. Table 35.1–3 shows the nine temperamental categories and three distinctive constellations of temperament as defined by Stella Chess and Alexander Thomas. The goodness of fit, or degree of consonance between the child's temperament and the parents' expectations or demands of the child, is an important predictor of future development and parent–child interactions.

Table 35.1–3.
Temperament Categories

Activity level: The motor component present in a given child’s functioning and the diurnal proportion of active and inactive periods.

Rhythmicity (regularity): The predictability or unpredictability in time of any function; it can be analyzed in relation to the sleep–wake cycle, hunger, feeding pattern, or elimination schedule.

Approach or withdrawal: The nature of the initial response to a new stimulus, be it a new food, a new toy, or a new person. Approach responses are positive, whether displayed by mood expression (e.g., smiling and verbalizations) or motor activity (e.g., swallowing a new food, reaching for a new toy, and active play). Withdrawal reactions are negative, whether displayed by mood expression (e.g., crying, fussing, grimacing, and verbalizations) or motor activity (e.g., moving away, spitting new food out, and pushing new toy away).

Adaptability: Responses to new or altered situations. One is not concerned with the nature of the initial responses, but with the ease with which they are modified in a desired direction.

Threshold of responsiveness: The intensity level of stimulation needed to evoke a discernible response, irrespective of the specific form of the response or the sensory modality affected. The behaviors used concern reactions to sensory stimuli, environmental objects, and social contacts.

Intensity of reaction: The energy level of response, irrespective of its quality or direction.

Quality of mood: The amount of pleasant, joyful, and friendly behavior (as contrasted with unpleasant, crying, and unfriendly behavior).

Distractibility: The effectiveness of extraneous environmental stimuli in interfering with or altering the direction of the ongoing behavior.

Attention span and persistence: *Attention span* concerns the length of time a particular activity is pursued by the child. *Persistence* refers to the continuation of an activity in the face of obstacles to the maintenance of the activity direction.

Qualitative analysis, supplemented by factor analyses, led to the formulation of, in addition, three constellations of temperament made up of various combinations of the individual categories, which appeared to have functional significance. These are as follows:

Easy temperament: The combination of biologic regularity, approach tendencies to the new, quick adaptability to change, and a predominantly positive mood of mild or moderate intensity. This group comprised approximately 40% of the study population.

Difficult temperament: The opposite of easy temperament, namely, biologic irregularity, withdrawal tendencies to the new, slow adaptability to change, and frequent negative emotional expressions of high intensity. This group comprised approximately 10% of the study population.

Slow-to-warm-up temperament: Withdrawal tendencies to the new, slow adaptability to change, and frequent negative emotional reactions of low intensity. Such individuals are often labeled shy. This group comprised approximately 15% of the study population.

Adapted with permission from Chess S, Thomas A. Temperament and its clinical applications. In: Lewis M, ed. Child and Adolescent Psychiatry: *A Comprehensive Textbook*. 3rd ed. Lippincott Williams & Wilkins; 2002:221.

Particularly salient aspects of the parental interview include a detailed history of the parents' childhoods and history of care, out-of-home placement, separations, and experience in their families of origin. The effect of the child on each parent and their marital relationship should be assessed, as well as the appropriateness and degree of congruity in their respective expectations of the child.

Adequate caregiving for the young child requires a delicate balance among gratification, comfort, support, and frustration that is appropriate to the child's developmental phase. It is important to hear (and to observe) which aspects of parenting and which features of the child's behavior the parent feels most comfortable with or most challenged by. The clinician should assess the parents' overall level of psychological functioning; the parental difficulties that adversely affect a young child's development do not always involve such gross failures as serious neglect or abuse but may involve problems more difficult to identify, such as persistent maternal or paternal depression. To help obtain a concrete picture of the parent, child, and their interaction, it is useful to ask for a detailed description of a typical day in the life of the child. In addition to providing data regarding the child's capacities, responses, and temporal organization, such a description provides clues to the parents' attunement and affective responses to the various elements of the child's behavior.

Although much of the clinical observation is focused on the child's behavior and capacities, direct observation of the parent–child relationship is essential. Inviting the family to interact in the playroom as they usually would at home allows observation of their interaction in unstructured parent–child or family play; assigning various structured tasks may also be useful. Observing the child in interaction with each parent separately helps to reveal relationship-specific patterns of behavior. Among the dimensions of parental behavior to be assessed are the ability to engage the child (verbally and nonverbally); the quality and affective tone of this engagement; the parent's attunement to the child's cues; parental vigilance, protectiveness, and limit setting; the parent's facilitation or restriction of autonomous play by the child; thematic content; and the degree of mutual pleasure, joint attention, and social referencing during play. Instruments and methodologies exist for formally assessing parental responsivity and parent–young child interaction, such as the Home Observation for Measurement of the Environment (HOME) and the Parent–Child Early Relational Assessment (PCERA). Some of these use standardized protocols or structured video recording and analysis. Some yield impressionistic global scores, whereas others provide detailed frame-by-frame coding of parent–child interactions. Although these methods are used primarily for research purposes, familiarity with the various facets of such instruments is clinically useful.

Observation and Examination of the Infant and Toddler

The direct examination of the young child draws on three levels of observation: The child's response to structured assessment items during formal testing, the child’s response to other interactions with the assessor and the assessment environment, and the spontaneous interactions of the child and parent in both clinical and naturalistic settings. When observation of the child and parents takes place in the clinic, it is essential to remember that the unfamiliar setting may elicit behavior that is not characteristic of the home setting; for this reason, it is important for the clinician to continuously inquire of the accompanying parent or caregiver as to whether the behaviors being observed are typical for the child.

Structured Assessment Instruments. A variety of instruments exists for the structured assessment of infants and young children, and each has somewhat different goals, theoretical orientation, and psychometric properties (Table 35.1–4). These instruments do not yield diagnoses; they detail the child’s development in various areas relative to a normative population. Some of these developmental tests are screeners designed to help pediatricians or trained paraprofessionals identify children with significant motor, social, or language delays who need fuller evaluation, whereas others are complete batteries evaluating a full range of developmental competencies. For example, the Bayley Scales of Infant and Toddler Development, Fourth Edition (Bayley-4), which is administered by a trained assessor, can be used to assess children 16 days to 42 months of age; it includes scales yielding standard scores for cognitive abilities, gross and fine motor skills, receptive and expressive communication, social-emotional, and adaptive (self-help) competencies, as well as a behavior rating scale for assessing qualitative aspects of the child’s behavior during the assessment. The assessment now includes special guidance for telepractice.

Although tests such as the Bayley-4 may show good reliability and concurrent validity, their ability, when administered to children younger than 3 years, to predict later performance on intelligence quotient (IQ) assessments or later adaptive functioning is weak. Among the reasons for this weakness of prediction are sources of error, such as the rapid pace of development during this period and the child’s susceptibility to state or environmental effects (e.g., fatigue and unfamiliar test setting), as well as the intervening effects of social and family environment and the heavy emphasis infant tests place on perceptual and motor skills that may have relatively little to do with information-processing capacities. However, very low scores on repeated measures are highly suggestive of continuing difficulties and warrant periodic follow-up assessment within the context of early intervention services to track development and to evaluate and refine intervention goals, intensity, and effectiveness.

The mental status examination of the infant and young child can be organized using a schema such as that shown in Table 35.1–5.

Diagnostic Formulation of the Assessment of Infants and Young Children

Although intellectual disability and autism spectrum disorders can be at least tentatively diagnosed in infants and toddlers, the most widely used official diagnostic system—the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and the eleventh revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-11)—generally lack a developmental perspective and diagnostic criteria or categories suitable for infants and young children. Zero to Three's *DC:0-5 Diagnostic Classification of Mental Health and Development Disorder of Infancy and Early Childhood, Version 2.0* (DC:0-5 Version 2.0) provides a diagnostic schema for this age group that complements the DSM and ICD.

The appropriate outcome of a thorough clinical assessment of the young child thus extends far beyond an attempt at a specific categorical diagnosis. The diagnostic formulation should provide a detailed picture of the strengths and challenges in the child's social, emotional, cognitive, linguistic, motor, and perceptual development; the quality of the child's temperament, attachment, and regulatory capacities; hypotheses regarding the etiology of the child's difficulties; and potential exacerbating or risk factors and protective or ameliorative factors in the child and family. This formulation, which should be shared with the family in a comprehensible and usable form, should provide the basis for recommendations regarding intervention or further assessment.

SPECIAL TYPES OF ASSESSMENT

This section describes the comprehensive clinical assessment of the child. Although the clinician must be aware of the many facets of history taking, interview, and observation described here, certain clinical settings or tasks may call for a narrower focus of inquiry or distinctive emphasis for the evaluation. For example, an urgent situation may require therapeutic intervention before a comprehensive assessment can be completed; in such cases, the immediate evaluation focuses on defining the crisis and selecting the most suitable immediate intervention. Thus, the emergency room or crisis center evaluation focuses on precipitants and extent of the current decompensation, predisposing vulnerabilities, the exacerbating factors affecting the child and family and the ameliorative resources available to the family in such situations, the risk of danger to self or others, and other issues germane to making an immediate disposition (including assessing the potential need for hospitalization). The assessment of suicidal ideation, threats, or attempts or aggressive outbursts is perhaps the most common clinical context for such urgent evaluations. Children exposed to acute trauma (e.g., natural catastrophe or violence) are often screened outside of the traditional clinic setting in a combination of emergency assessment and crisis intervention. The noncompliant, acutely agitated, or delirious child in the pediatric setting raises yet another set of assessment issues (Table 35.1–6).

Various specialized consultative purposes also require distinctive techniques or procedures or specific areas of inquiry. (The American Academy of Child and Adolescent Psychiatry has prepared valuable practice parameters providing guidance for assessment and treatment of children and adolescence in forensic settings, detention or correctional facilities, schools, community systems of care, and pediatric settings, as well as youngsters presenting with certain specific conditions, such as substance abuse, suicidal behaviors, aggression, exposure to trauma, etc.)

For example, forensic evaluations raise special issues of role definition, confidentiality, and privilege and require familiarity with the legal issues involved. Clinicians must be clear about whether they are serving as neutral impartial advocates for the best interests of the child at the behest of the court or as consultants to one party or another. Although the clinician treating or assessing the child for clinical purposes may have information valuable to a forensic evaluation, it is usually in the best interests of the therapy and the legal proceedings for the evaluator to be someone other than the therapist.

The assessment of children or adolescents who may have been physically or sexually abused is a common form of forensic evaluation. In addition to assessing the child's competency and credibility, the examiner may also be asked for recommendations regarding whether the child should testify in court (and, if so, how) and whether removal of the child or alleged perpetrator from the home is needed, as well as any therapeutic interventions that may be required. A forensic evaluation requires careful documentation of parent and child interviews. The suggestibility of younger children raises the danger of false accusations and false denials and requires meticulous safeguards against repetitive, suggestive questioning.

Table 35.1–4.
Selected Formal Tests of Infant and Toddler Development

	Age	Domains[a]	Norm Sample	Reliability/Validity	Comments
Neonatal					
Assessment Tests					
Graham/Rosenblith Behavioral Examination of Neonates		M, TA, V, A, MT	Not applicable	Encouraging early findings	Currently seldom used
Brazelton Neonatal Behavioral Assessment Scale—2	37–44 weeks gestational age	NI, B, PS	Not applicable	High interrater reliability, weak test-retest, poor predictor beyond first year	Most widely used neonatal test
Infant/Toddler					
Development Tests					
Bayley Scales of Infant Development-4	16 days–42 months	Cg, GM/FM, EC/RC, Ad, SE, B	Large, representative	Excellent for mental, adequate for psychomotor, varied for behavior	Most widely used and validated infant test
Mullen Scales of Early Learning	0–68 months	GM, FM, VR, RC, EC	Large, representative	Adequate to exceptional	Mostly useful for toddlers and preschoolers
Battelle Developmental Inventory—3	0–95 months	Comm, SE, Ad, M, Cg (and sub-domains)	Small, representative	Numerous psychometric concerns cast significant doubts (see text)	Used considerably, despite many test flaws
Griffiths Abilities of Babies	0–24 months	Lm, PS, HS, EH, P	Small, all from London	Mixed results	Mostly used in Europe
Infant–Toddler Developmental Assessment—2	0–36 months	GM, FM, RIO, Lang/Comm, Ad, RP, SE, Cop	Not applicable	Excellent reliability	Multi-informant, criterion referenced
Screening Tests					
Battelle Developmental Inventory—3 Screening Test	6–95 months	Comm, SE, Ad, M, Cg	Small, representative	Strong correlation with full BDI	Suffers same limitations as full BDI
Bayley Scales of Infant and Toddlers Development Screening Test—4	16 days–42 months	Cg, Lang, M	Large; representative	Excellent reliability; promising validity	
Child Development Inventory	15–72 months	GM, FM, EC, RC, Ad, PS, L, N	Small; from St. Paul, MN	Little evidence of reliability and validity	300 parent report items
Developmental Activities Screening Inventory—II	0–60 months	15 sensory and problem-solving areas	>200 disabled children	Little evidence of reliability; valid for severely delayed	Can be used with language- and visually impaired children
Developmental Indicators for the Assessment of Learning—4	30–71 months	M, Lang, Cg	Large; representative	Acceptable reliability and validity	One of the better screeners for age level
Diagnostic Inventory for Screening Children—4	0–60 months	FM, GM, RC, EC, AM, VM, Ad, PS	Small; all from southwest Ontario	Excellent reliability; limited validity	
Developmental Observation Checklist System	0–72 months	Cg, EC/RC, PS, FM/GM, Adj, PS&S	Adequate; representative	Sound reliability and concurrent validity	Parent report only
Developmental Profile—4	0–21 years, 11 months	M, Ad, PS, AS, EC/RC	Large	Adequate reliability and validity	Parent report, teacher checklist, clinician rating
Early Screening Profile	24–71 months	Cg, EC/RC, M, Ad/PS, Ar	Adequate; representative	Good reliability; exceptional validity	One of better screeners for age level
Kent Infant Development Scales	0–12 months	Cg, M, EC/RC, Ad, PS	All from Northeast Ohio	Adequate reliability and validity	Primarily parent report

[a] A, auditory responsiveness; Ad, adaptive, self-help or daily living; AM, auditory attention and memory; Ar, articulation; AS, academic or pre-academic skills; B, behavior; Cg, cognitive or problem-solving; Cop, coping; EC, expressive communication/language; EH, eye-hand coordination; FM, fine motor; GM, gross motor; HS, hearing and speech; L, letters; Lm, locomotor; M, motor or physical; MT, muscle tone; N, numbers; NI, neurologic intactness; P, performance; PS, personal-social; PS & S, parental stress and support; RC, receptive communication/language; RIO, relationship to inanimate objects; RP, relationship to persons; SE, social-emotional; TA, tactile-adaptive; V, visual responsiveness; VM, visual attention and memory; VR, visual reception. A slash mark (/) indicates that multiple domains are assessed in the same scale or subtest.

Table 35.1–5.
Infant and Toddler Mental Status Examination[a]

I. Appearance

Size, level of nourishment, dress and hygiene, apparent maturity compared to age, dysmorphic features (e.g., facies, eye and ear shape and placement, epicanthal folds, and digits), abnormal head size, cutaneous lesions.

II. Apparent reaction to situation

Note where and with whom the evaluation takes place.

- A. Initial reaction to setting and to strangers: Explores; freezes; cries; hides face; acts curious, excited, apathetic, or anxious (describe).
- B. Adaptation
  1. Exploration: When and how child begins exploring faces, toys, stranger.
  2. Reaction to transitions: From unstructured to structured activity; when examiner begins to play with infant; cleaning up; leaving.

III. Self-regulation

- A. State regulation: An infant's state of consciousness ranges from deep sleep through alert stages to intense crying. Predominant state and range of states observed during session, patterns of transition (e.g., smooth vs. abrupt), capacity for being soothed and self-soothing, capacity for quiet alert state. (Some of these categories also apply to toddlers.)
- B. Sensory regulation: Reaction to sounds, sights, smells, light and firm touch; hyperresponsiveness or hyporesponsiveness (if observed) and type of response, including apathy, withdrawal, avoidance, fearfulness, excitability, aggression, or marked behavioral change; excessive seeking of particular sensory input.
- C. Unusual behaviors; mouthing after 1 year of age; head banging; smelling objects; spinning; twirling; hand flapping; finger flicking; rocking; toe walking; staring at lights or spinning objects; repetitive, perseverative, or bizarre verbalizations or behaviors with objects or people; hair pulling; ruminating; or breath holding.

D. Activity level: Overall level and variability (note that toddlers are often incorrectly called hyperactive). Describe behavior; for example, squirming constantly in parent’s arms, sitting quietly on floor or in infant seat, constantly on the go, climbing on desk and cabinets, exploring the room, pausing to play with each of six to eight toys.

E. Attention span: Capacity to maintain attentiveness to an activity or interaction, longest and average length of sustained attention to a given toy or activity, distractibility. Infants: Visual fixing and following at 1 months of age, tracking at 2–3 months of age, attention to own hands or feet and faces, duration of exploration of object with hands or mouth.

F. Frustration tolerance: Ability to persist in a difficult task, despite failure; capacity to delay reaction if easily frustrated—e.g., aggression, crying, tantrums, withdrawal, and avoidance.

G. Aggression: Modes of expression, degree of control of or preoccupation with aggression, appropriate assertiveness.

IV. Motor

Muscle tone and strength, mobility in different positions, unusual motor pattern (e.g., tics and seizure activity), intactness of cranial nerves (e.g., movement of face, mouth, tongue, and eyes, including feeding, swallowing, and gaze [note excessive drooling]).

A. Gross motor coordination. Infants: Pushing up, head control, rolling, sitting, standing. Toddlers: Walking, running, jumping, climbing, hopping, kicking, throwing, and catching a ball. (It is useful to have something for the child to climb on, such as a chair.)

B. Fine motor coordination. Infants: Grasping and releasing, transferring from hand to hand, using pincer grasp, banging, throwing. Toddlers: Using pincer grasp, stacking, scribbling, cutting. Fine motor and visual-motor coordination can be screened by observing how the child handles puzzles, shape boxes, a ball and hammer toy, small cars, and toys with connecting parts.

V. Speech and language

A. Vocalization and speech production: Quality, rate, rhythm, intonation, articulation, volume.

B. Receptive language: Comprehension of others' speech as seen in verbal or behavioral response (e.g., follows commands), points in response to "where is" questions, understands prepositions and pronouns (include estimate of hearing, especially in child with language delay, e.g., response to loud sounds and voice; ability to localize sound).

C. Expressive language: Level of complexity (e.g., vocalization, jargon, number of single words, short phrases, and full sentences); overgeneralization (e.g., uses *kitty* to refer to all animals); pronoun use, including reversal; echolalia, immediate or delayed; unusual or bizarre verbalizations. Preverbal children: Communicative intent (e.g., vocalizations, babbling, imitation, and gestures, such as head shaking and pointing), caregiver's ability to understand infant's communication, child's effectiveness in communication.

VI. Thought

The usual categories for thought disorder almost never apply to young children. Primary process thinking, as evidenced in verbalizations or play, is expected in this age group. The line between fantasy and reality is often blurred. Bizarre ideation, perseveration, apparent loose associations, and the persistence of pronoun reversals, jargon, and echolalia in an older toddler or preschooler may be noted in a variety of psychiatric disorders, including pervasive developmental disorders.

A. Specific fears: Feared object, worry about being lost or separated from parent.

B. Dreams and nightmares: Content is sometimes obtainable in children 2–3 years of age. Child does not always perceive it as a dream; for example, "A monster came in the front door."

C. Dissociative state: Sudden episodes of withdrawal and inattention, eyes glazed, "tuned out," failure to track ongoing social interaction. Dissociative state may be difficult to differentiate from an absence seizure, depression, autism, or deafness. The context may be helpful (e.g., a child with a history of neglect freezes in a dissociative state as mother leaves the room). Neurologic or audiologic evaluation may be warranted.

D. Hallucinations: Extremely rare, except in the context of a toxic or medical disorder, then usually visual or tactile.

VII. Affect and mood

The assessment of mood and affect may be more difficult in young children because of limited language, lack of vocabulary for emotions, and use of withdrawal in response to a variety of emotions, from shyness and boredom to anxiety and depression.

A. Modes of expression: Facial, verbal, body tone and positioning.

B. Range of expressed emotions: Affect, especially in parent–child relationship.

C. Responsiveness: To situation, content of discussion, play, and interpersonal engagement.

D. Duration of emotional state: Need history or multiple observations.

E. Intensity of expressed emotions: Affect, especially in parent–child relationship.

VIII. Play

Play is a primary mode of information gathering for all sections of the Infant and Toddler Mental Status Examination. In young children, play is especially useful in the evaluation of the child’s cognitive and symbolic functioning, relatedness, and expression of affect. Themes of play are helpful in assessing older toddlers. The management and expression of aggression are assessed in play as in other areas of behavior. Play may be with toys or with the child’s own or another’s body (e.g., peek-a-boo, roughhousing), verbal (e.g., sound imitation games between mother and infant), or interactional or solitary. It is important to note how the child’s play varies with different familiar caregivers and with parents versus the examiner.

A. Structure of play (ages are approximate).
   1. Sensorimotor play
      a. 0–12 months of age: Mouthing, banging, dropping and throwing toys or other objects.
      b. 6–12 months of age: Exploring characteristics of objects (e.g., moving parts, poking, and pulling).
   2. Functional play
      a. 12–18 months of age: Child's use of objects shows understanding and exploration of their use or function (e.g., pushes car, touches comb to hair, and puts telephone to ear).
   3. Early symbolic play
      a. 18 months of age and older: Child pretends with increasing complexity; pretends with own body to eat or to sleep; child pretends with objects or other people (e.g., "feeds" mother); child uses one object to represent another (e.g., a block becomes a car); child pretends a sequence of activities (e.g., cooking and eating).
   4. Complex symbolic play
      a. 30 months of age and older: Child plans and acts out dramatic play sequences, uses imaginary objects. Later, child incorporates others into play with assigned roles.
   5. Imitation, turn taking, and problem solving as part of play.

B. Content of play. The toddler's choice and use of toys often reflect emotional themes. It is desirable to have on hand toys that tap different developmental and emotional domains. An overfull playroom may be overwhelming or overstimulating and may reduce meaningful observations. Young toddlers of both sexes often gravitate to dolls, dishes, animals, and moving toys, such as cars. The examiner's choice of specific materials may facilitate the expression of pertinent emotional themes. For example, a child traumatized by a dog bite may more likely re-enact the trauma if a dog and doll figures are available. The child's reaction to scary toys, such as sharks, dinosaurs, or guns, should be noted, especially if they are avoided or dominate the session. Does aggressive pretend play become real and physically hurtful? By 2.5–3 years of age, a child's animal or doll play can reveal important themes about family life, including reactions to separation, parent–child and sibling relationships, experiences at day care, quality of nurturance and discipline, and physical or sexual abuse. The examiner must use caution in interpreting play, viewing it as a possible combination of re-enactment, fears, and fantasy.

IX. Cognition

Using information from all previously mentioned areas, especially play, verbal and symbolic functioning, and problem solving, roughly assess the child's cognitive level in terms of developmental intactness, delays, or precocity.

X. Relatedness

A. To parents: How in tune do the child and parent seem? Does the child make and maintain eye, verbal, or physical contact? Is there active avoidance by child? Note the infant's level of comfort and relaxation being held, fed, molding into caregiver's body. Does the toddler move away from the caregiver and check back or bring toys to show, to put into their lap, to play with together or near the caregiver? Comment on physical or verbal affection, hostility, reaction to separation and reunion, and use of transitional objects (blanket, toy, caregiver's possession). Describe differences in relating if more than one caregiver is present.

B. To examiner: Young children normally show some hesitancy to engage with a stranger, especially after 6–8 months of age. Appropriate wariness in young children may result in a period of watching the examiner, staying physically close to a familiar caregiver before engaging, or showing some constriction of affect, vocalization, or play. After initial wariness, does the child relate? Does the child engage too soon or not at all? How does relatedness with a stranger compare to that with a parent? Is the child friendly versus indiscriminately attention seeking or guarded versus overanxious? Can the examiner engage the child in play or structured activities to a degree not seen with caregiver? Does the child show pleasure in successes if the examiner shows approval?

C. Attachment behaviors: Observe for showing affection, seeking comfort, asking for and accepting help, cooperating, exploring, controlling behavior, and responding to reunion. Describe age-related disturbances in these normative behaviors. Disturbances often are seen in abused and neglected children; for example, fearfulness, clinginess, overcompliance, hypervigilance, impulsive overactivity, and defiance; restricted or hyperactive and distractible exploratory behavior; and restricted or indiscriminate affection and comfort seeking.

Child custody evaluations also require careful definition of the assessor’s role with all concerned. Specific attention must be given to the best interests of the child in terms of continuity and stability of care, the quality of parent–child attachment and attunement, the child’s stated preferences, the mental health of each parent, and the level of parental conflict and its effect on the child. Consultations for the juvenile court regarding youthful offenders or children in need of services and probate or commitment hearings represent other forms of forensic evaluation. Other specialized forms of evaluation include medication consultations and consultation to day care centers, schools, or pediatric specialty clinics (e.g., pain or oncology clinics).

STANDARDIZED ASSESSMENT INSTRUMENTS FOR CHILDREN AND ADOLESCENTS

While, as discussed earlier, psychosocial and environmental factors must inform clinical decision-making, the systematic assessment of symptoms, behavior and impairment is an essential part of clinical evaluation. Numerous tools—diagnostic interviews and rating scales—have been developed that elicit comprehensive information about psychiatric symptoms and diagnoses. The use of such tools provides some protection against the risks to which traditional clinical approaches may be prone, for example, tendencies to make diagnoses too quickly, collecting information selectively that confirms initial impressions, ignoring contradictory information, and applying diagnostic criteria idiosyncratically. The relatively structured diagnostic measures are likely to yield more reliable diagnoses than those made from less systematic approaches, and these features in turn improve the likelihood of obtaining meaningful findings from research efforts, which depend on assessing diagnoses in a consistent manner across a large number of study participants. However, although structured interviews and scales can be useful for certain purposes, as discussed below, for clinical purposes they cannot take the place of an individualized clinical psychiatric interview by an experienced clinician that takes into account individual, family, and situational contexts that are crucial for assessment and treatment planning.

Response to immobilization
Denial
Idiosyncratic sources of anxiety
Inadequate pain control
Depression
Exacerbation of pre-existing psychopathology, especially oppositional or conduct difficulties
Family issues
Parental anxiety or hostility toward staff
Parental psychopathology: Depression, psychosis, or factitious disorder by proxy
Prior family experiences with illness
Cultural issues
Developmental issues (especially adolescence)
Emphasis on autonomy, ambivalence regarding dependency
Emphasis on activity, peer involvement
Self-consciousness about body
The body as a means of expressing psychological issues
Mature decision to refuse treatment

Reprinted from King RA, Lewis M. The difficult child. *Child Adolesc Psychiatr Clin N Am.* 1994;3(3):531–541. doi: 10.1016/S1056-4993(18)30485-1.

The advent of many of these tools can be traced to two related developments in psychiatric clinical thinking and research since 1980. First, the introduction of explicit, criterion-based diagnostic systems beginning with the Research Diagnostic Criteria and the DSM-III, followed by the DSM-III-R, the DSM-IV, and the DSM-5, as well as the research version of the ICD-10 facilitated the development of standardized interviews and questionnaires, which specify the relevant elements of a diagnosis. Second, at the same time, there has been a rapid expansion in psychiatric research, creating a need for tools for research assessment. Thus, working synergistically, major changes in the diagnostic system, the impetus provided by emerging research findings, and the increasingly apparent advantages of using standardized diagnostic tools in research (and, subsequently, in clinical settings) are key developments that have presented the field with an array of psychiatric assessment techniques and thus with a corresponding growing body of research literature on their characteristics and utility.

Because the inventory of symptomatic and diagnostic tools for children and adolescents has rapidly expanded over recent years, it is important for those evaluating and treating youth to become familiar with the literature and with the clinical and research relevance of these tools.

Issues in Developing Diagnostic Methods

The task of developing diagnostic tools for psychiatric and mental health assessment is a complex and challenging one, given the complicated nature of the symptoms and their clusters and patterns over time. In addition, developing measures to assess psychopathology in children and adolescents is more challenging than the comparable task with adults. These challenges include the need to incorporate an understanding of aspects of development into the framing and wording of questions about symptoms and into the process of discriminating normative from pathologic behaviors. Many behaviors only become “symptoms” when they occur at too high a frequency or at the wrong age (e.g., separation problems and oppositional behaviors), or cause functional impairment. In addition, many symptoms reflect an underlying substrate of psychopathology with phenotypic manifestations that differ during different developmental stages. Moffit referred to these variations as a function of the “heterotypic continuity” of disorders. Severe irritability provides an illustrative example: what is difficult temperament in early months and years may progress to the characteristics of disruptive mood dysregulation disorder in middle childhood and adolescence, and eventually become manifest as adult anxiety and depression.

Another challenge in the development of structured interviews or scales is the necessity of obtaining information from both the child and another informant, usually the parent and at times the teacher, paralleling what is done in good clinical practice, because developmental stage can limit the capacity of children to report on their own behaviors/symptoms. Not surprisingly, investigators have repeatedly found poor agreement between different informants with respect to symptom presence and hence diagnosis; yet, as has long been realized by clinicians, there is general agreement that information obtained from any informant is diagnostically useful. There is no consensus, however, in using these tools, on how best to combine the information across informants or as to whether to combine the information at all. Some kinds of information may be uniquely accessible to one or another informant—for example, teachers may be better reporters of attention problems than parents, whereas parents are likely to be better reporters of eating behaviors and irritable mood. For alcohol or other substance use, youth consistently report more symptoms than parents do, and similar results have been found for sexual behavior, suicidality and self-injurious behaviors, and conduct disorder.

Characteristics of informants may influence how they report on symptoms and behavior. Parents who have anxiety disorders tend to report greater levels of psychiatric symptoms in their children than do independent observers. Mothers who are depressed tend to over-report behavior problems and symptoms in their children, even when contextual variables and child gender have been controlled for. Complicating this issue, children of depressed mothers have been found to have more behavioral problems than children of nondepressed mothers. At younger ages, children often do not have the ability to compare themselves to others, which can affect their reports on oppositional behavior or hyperactivity.

Further challenges to the development of diagnostic measures include the problem of how to integrate concepts of social context and adaptive functioning into a symptom-based assessment. These factors are difficult to isolate conceptually and to operationalize without producing an overly long and complex measure.

In the history of diagnostic methodologic development, the psychometric properties of reliability and validity have been touted as the basis for determining what measure was best. It is important for users to understand these concepts and to be familiar with a proposed instrument's performance in these respects. Briefly, the *reliability* of an assessment method is often conceptualized as the extent to which the results of an assessment can be repeated or reproduced, whereas *validity* is conceptualized as the extent to which the instrument measures what it purports to measure.

There are various types of reliability. *Inter-rater reliability* involves the stability of an assessment when it is administered by different raters (in the case of psychiatric diagnostic interviews, by different interviewers). *Test–retest reliability* reflects the stability of results across administrations, that is, when an instrument is administered on two occasions, separated by a period of time in which the degree of real change in the condition being measured is expected to be trivial, and seeing if the two administrations agree with one another. To assess the test–retest reliability of child psychiatric diagnostic instruments, the measure is often administered twice, 1 to 2 weeks apart. The 1-to-2-week interval is chosen to minimize precise memory effects (i.e., the child or parent is not likely to remember, and thus repeat, exact responses to a great number of the questions previously asked). The relatively long duration of many child psychiatric conditions makes it likely that changes between the first and second administrations reflect unstable aspects of the measure rather than real changes in the disorder. For instruments which use interviewers, assessment of test–retest reliability is particularly complicated as a different interviewer typically administers the "retest" interview. This is necessary for two reasons. First, taking the same assessment from the same interviewer a second time may lead the respondent to leave out symptom reports, assuming that the interviewer already knows about the respondent's experience with an area of symptomatology or, conversely that the phenomena should be reported differently because the interviewer is going over the same issues a second time. Second, the interviewers themselves may recall the first interview and this knowledge might lead them (consciously or unconsciously) to conduct the second interview differently than they would with a respondent they did not already know. Thus, test–retest reliability for diagnostic interviews will necessarily be somewhat limited by inter-rater reliability. In addition, discrepancies between the initial administration and the subsequent interview usually result from the informant reporting fewer symptoms at the second administration—the "attenuation effect." This has been found in all forms of repeated psychiatric inquiry and likely represents a systematic bias in reporting. *Internal consistency* is a third type of reliability and refers to the extent to which items designed to assess aspects of a known disorder (e.g., depression) are measuring the same underlying construct. In omnibus measures, the internal consistency of different diagnoses or domains may be assessed separately because these instruments by design assess a wide range of behaviors and symptoms rather than a single construct. Thus, the component items for each diagnosis would not be expected to correlate with the items from other diagnoses.

The *validity* of a measure is more difficult to determine than its reliability. There are various ways to conceptualize and assess validity. To assess what is termed *construct validity,* the psychiatric diagnoses or scores generated by a particular instrument are usually compared to those generated by an expert, or criterion, assessment. Statistical methods are then applied to quantify the degree of agreement about whether diagnoses are present or absent. (In the methodologic evaluation of the validity of an omnibus diagnostic instrument, agreement is determined diagnosis by diagnosis, so that it can be revised in areas of poor agreement with the criterion.) The essential challenge in determining the construct validity of a measure is to compare its performance to some standard that is known to be diagnostically correct. A central problem in the field of psychiatric assessment is the lack of a readily available "gold standard" with which to compare results because there is no laboratory test or other agreed upon standard to provide objective evidence for the presence of a disorder. Clinical assessments of child psychiatric diagnoses are notorious for varying from one clinician to another; thus, the so-called “standard” is a moving target. Indeed, structured interviews and scales were developed in large part to improve the poor psychometric properties of nonstandard assessments. This situation has led to an approach that considers an instrument’s performance within the nomologic net of theory and findings about the condition being assessed. Stated briefly, this means that, to the degree that an instrument’s findings converge with accumulated thinking and knowledge in the field, one may have relative confidence that, at least at this point, the instrument validly measures what it claims to assess. The major diagnostic assessments have shown considerable convergence in their evidence for reliability and validity; thus, in the complex process of instrument development, it is important to be aware when a new measure is falling below existing standards in these respects.

Despite—or perhaps because of—these various challenges, extensive research efforts have been directed toward refining psychiatric assessment methods in child and adolescent psychiatry. These endeavors have yielded a number of measures for use in research contexts; in addition, some of those described in the following discussion have also found appropriate adjunctive roles in clinical settings. The following discussion of methods first examines interview methods, which yield categorical diagnoses, and then reviews scales that cover symptom dimensions, often with respect to a specific form of psychopathology, for example, depressive symptoms.

Diagnostic Interviews

There are numerous “omnibus” diagnostic interviews for children and adolescents. In clinical settings, such interviews might be included as a supplementary part of the diagnostic evaluation to ensure that major symptoms domains are assessed and to guide treatment, triage or planning. Most of these diagnostic interviews are designed to be administered to the youth’s parent (about the child/adolescent) and, depending on the youth’s age, separately to the young person. Although the exact contents of the various diagnostic interviews differ, each covers a wide range of the more common psychiatric disorders of childhood and adolescence, although many do not include the autism spectrum disorder. Each version addresses the DSM diagnostic criteria (and often the ICD criteria as well), and updates for DSM-5 have either been prepared or are underway. (Of note, when moving from DSM-IV to DSM-5, with the exception of Autism, few changes were made to the DSM criteria for disorders that typically affect youth, so it is not necessary to restrict oneself to considering only DSM-5 measures.)

The omnibus diagnostic interviews differ from one another in several important respects, which should be taken into account when choosing among them. The first issue to consider is the *purpose* of the assessment (e.g., to identify a participant for research or to address a need for clinical treatment or triage? to establish diagnosis(es)? to identify co-morbidity? to measure severity?). Consideration of the purpose of the assessment also involves the time frame of interest (current only? past year? ever? current and ever?). Practical issues also inform plans for implementation, including: how long it takes to administer the interview; whether the same interviewer must interview both parent and youth; qualifications for administrators or interviewers (is it necessary to have a clinician administer the assessment?); the standard training procedures and supervision; scoring procedures (are there specific rules or algorithms? is a computer program necessary; if so, what are the available reports? is scoring based on clinical judgment? is an expert editor/reviewer necessary? how transparent is the scoring? what data will the interview yield—diagnoses only or symptoms and scales as well?); infrastructure considerations (necessary staff, computer/analytic capabilities; office space to conduct private interviews); and, finally, costs (including license fees, copying, storage).

Also, if the sample contains cultural subgroups, one must consider whether the style of the interview, especially language used in asking about symptoms and behavior, is suitable for the group(s) to be interviewed. In such instances, a pretest on a subsample with a post-administration focus group may suggest expansion of question(s) about particular symptoms or additional culturally more sensitive wording to cover the same symptoms. *In all instances*, it is strongly recommended that before choosing an instrument one obtain a copy of the interviews under consideration and critically review their contents to understand how symptoms and criteria are conceptualized by their authors and whether one agrees with the conceptualizations.

Respondent-Based versus Interviewer-Based Interviews. Perhaps the most fundamental distinction between the different diagnostic interviews is the degree of structure they impose. Terms often used to describe this are “highly structured” versus “semi-structured,” but a more useful way to think about this is a “respondent-based” versus an “interviewer-based” approach. The respondent-based interview (RBI) has been described by Shaffer and colleagues as a “precise script” to obtain clinical information from the informant. The RBI has precisely worded and ordered questions and equally structured response options; thus, the authors essentially transformed the diagnostic criteria into questions that should be easily understood. The RBI is totally dependent upon how clearly the questions are written and are understood by respondents. A primary question that is answered positively leads to a branching sequence of nested questions that specify symptom frequency, intensity, duration, and degree of associated impairment. These questions help determine the significance of the reported behavioral-emotional state and aim to determine whether it reaches a certain clinical threshold. Alternatively, an initial negative response allows “skip out” of these specific questions. The relative advantages of the RBI include the potential for methodologic development and also issues of economy and public health applicability. Because this type of interview is given in the same way each time, it is possible to study its performance and then modify it with a relative degree of confidence in the rationale for changes.

Another advantage is the potential for relatively economic data gathering and management. Because the structure of this type of interview drives its administration, a range of administrators (typically "lay" [clinically untrained] interviewers with little psychiatric/medical background) are used and some of these interviews can even be "self-administered" via computer where there is no interviewer and the informant either reads the questions themselves or the computer "asks" the questions. While it is more cost-effective to use self-administration with visual or auditory prompts or computer administration that bypasses the need for and the expense of interviewers, the limitations and potential risks of the RBIs must be considered. These include the risk of the child or youth finding the process impersonal and therefore not freely reporting symptoms, rushing through the evaluation by entering responses before thinking about what was is being asked (especially if the interview is lengthy), and not understanding questions, but still entering a response. However, the potential of RBIs as screening tools in community settings is another attractive aspect of this method.

A further cautionary word about RBI administration involves the use of nonclinically trained interviewers. While this is a real asset in terms of the available pool for hiring potential interviewers, there are important caveats. Nonclinically trained interviewers need to be coached in the importance of establishing appropriate rapport, often more difficult with children than parents. Good administration of an RBI involves more than just reading the questions as written. Interviewers need to be coached in how to establish an appropriately relaxed and welcoming attitude and rapport consistent with the sense that "we are here to do something important that means you will be asked a lot of questions about yourself. Do your best to answer them without worrying about the questions. If you need a stretch or short break to get a drink of water or use the restroom, just tell me…that's OK. Any questions? Good, let's get started!" If the interview process leads to the child/adolescent revealing something obviously painful, an understanding, empathic expression or sympathetic nod and slight pause may help the child/youth regroup. "I understand" may be appropriate, but the interviewer should not probe and should definitely report periods of distress (e.g., revelations of child abuse, breakdowns in composure) to the clinical supervisor. In addition, the interviewers must be trained in a protocol of what to do if clinically emergent information, such as suicidality, potential child abuse, etc., is reported.

In contrast to RBIs, interviewer-based interviews (IBIs) rely on the skills of the clinically trained interviewer to make sound judgments about the presence and clinical significance of reported phenomena. Thus, the IBI is totally dependent upon the interviewer's clinical skill and quality of training. IBIs contain some degree of structure, in that definitions are usually provided about what constitutes a symptom, but although questions are provided to prompt the clinician-administrator, it is expected that the interviewer will pursue inquiry until their clinical judgment is satisfied about whether a symptom is present. This allows for a degree of flexibility and responsiveness to the body of clinical data that are ordinarily used to determine the significance of reported emotions, moods, and behavior—for example, observation of affective state in response to a query or other observational data, such as eye contact, posture, and voice inflection.

Because the choice of interview type and then of the specific interview depend on the intended use, before selecting a measure, it is worthwhile to examine some of the extensive literature developed on these methodologies. Briefly, RBIs probably do not do well in diagnosing extreme and atypical phenomena (e.g., psychosis), because this method "assumes" that respondents (youth or parents) interpret the questions as intended by the interview developer and also that the respondent has the capacity to reflect and to self-observe about the presence or absence of the symptom. IBIs can be more flexible and responsive to the state of the respondent and hence could take less time to administer. For example, an astute clinician can usually assess manic symptomatology fairly quickly and efficiently in a previously high functioning youth. In practice, however, these interviews typically take as long or even longer as an RBI. In addition, when using an IBI the careful clinician should catch most instances of the respondent misunderstanding the intent of the question, whereas the RBIs have little capacity to self-correct for this inevitable source of error. IBIs, although more costly than RBIs to administer, are particularly appropriate for clinically based research in which subtle diagnostic distinctions may be critical for defining relatively diagnostically “pure” samples and in which sample sizes are small enough to justify the expense of hiring interviewers trained in making these judgments.

RBIs, however, as noted previously, have many flexible and innovative applications in research and public health contexts. They have also found recent application in an increasing number of clinical contexts, for example, as efficient aids in collecting comprehensive symptom and diagnostic information for outpatient clinic or even inpatient intake. Because they systematically review symptoms across all domains, this type of screen sometimes uncovers significant symptomatology, such as suicidal tendency, that was not queried or not revealed on initial clinical interview. But, while the RBIs are, to some extent, mechanical and lack the personal element of the skilled clinical interview, it has been shown that many adolescents, in particular, appreciate the privacy of the computer-based, self-report methods (a familiar modality for many youth).

RBIs are particularly useful for epidemiologic studies in which large sample sizes (i.e., in the thousands) require many interviewers either in person or, more recently, via telemeeting, thus making the use of trained clinicians prohibitively expensive. These studies investigate issues of the prevalence of disorders, developmental patterns of psychopathology, their distribution within psychosocial subgroups in the population, risk and protective factors, access and use of mental health services in relation to types of psychopathology, and other topics that require large samples to provide enough statistical power to examine the study hypotheses. The ultimate choice of a measure requires careful weighing of the goals that it is intended to serve, the resources available, and the pragmatics of the situation.

RBIs and IBIs have been developed with the goal of reducing error in the collection of information relevant to making diagnoses. Error in the counting and combining of symptom data to determine a diagnosis can be minimized with RBIs or IBIs by the use of specified algorithms, usually computer applied, to establish whether sufficient symptoms are present for the diagnosis and whether they meet DSM criteria for intensity, frequency, and duration. Ultimately, it remains an informed judgment call as to the method that best serves the ends of general appropriateness, including error reduction, logistics, and economy (relative to the intended goal). As opposed to period of the early 1980s following the advent of DSM-III when the development of structured and semi-structured instruments began, there now exists considerable theoretical and empirical information on which to base decisions about instrument choice.

Respondent-Based Interviews. The Diagnostic Interview Schedule for Children (DISC) is the most extensively developed and studied of the RBIs. The DISC was specifically designed for use in large epidemiologic and community studies where it could be administered by “lay” (clinically untrained) interviewers who would read questions verbatim to parent (concerning children ages 6 to 18) and to child (ages 9 to 18), with most structured so as to be answered “yes” or “no.” Since it appeared, the DISC has also been used in clinical research studies, screening projects, clinical treatment settings, and juvenile justice settings. Initial work on the DISC began in 1980 and since then it has gone through numerous updates to maintain alignment with the DSM system in its iterations, as well as with methodologic testing in both clinical and community settings. The recently completed DISC-5 is compatible with DSM-5, DSM-IV, and ICD-10 (research version), and, like the DISC-IV, assesses diagnoses over three different time frames—past 4 weeks, past year, and lifetime, although the accuracy of recall for the lifetime frame is questionable and hence those questions are optional. DISC diagnostic modules are self-contained, so that in a particular context the user might selectively administer only those modules of interest. In the DISC, a uniform question structure has been applied in that for each criterion being assessed, an initial stem question is asked, which if endorsed, is then followed by contingent questions that elicit increasingly more specific types of information about characteristics of the potential symptom. This structure allows probes to be shorter and contain few concepts, making them more easily understood by respondents. Given the complexity of information required for assigning DSM diagnoses, administration of the whole interview using paper protocols is not practical, so the DISC is given with the aid of a computer. Computer-assisted versions ensure fidelity to the intended structure of the questioning, as well as reducing the time needed for the interviewer to consider what the next question should be. In addition to symptom questions, the DISC includes questions in each diagnostic section that inquire about associated impairment and perceived severity of impairment. These questions are asked if a respondent meets a certain base level of symptomatology for a given diagnosis—about half of what would be required for a DSM diagnosis. For the DISC-IV, there was also a computerized version, the Voice-DISC, which can be self-administered; a comparable version is under development for DISC-5.

DISC diagnoses are derived by application of a set of computer algorithms. The interview has few symptom skips so that it is possible to generate symptom and DSM criterion scale scores, further increasing its flexibility and general usefulness, especially in research settings. Of importance, respondent acceptability has been demonstrated to be quite good, despite some (but not an overwhelming) perception that it is a bit lengthy. For the DISC-IV, a modified version, the Young Child DISC, is administered to parents only and is used to assess childhood symptomatology down to age 4. The Young Adult DISC-IV, with parallel self and “other informant” versions, was also available, and is being updated for DISC-5. A Spanish-language DISC-IV version was developed and extensively tested. The DISC-IV was translated into a number of other languages and found various innovative applications around the world. Particularly exciting applications are those in which it can assist in clinical contexts where trained mental health clinicians are in short supply (e.g., its use in juvenile justice facilities, orphanages, and regions of the world with few mental health practitioners per capita). Modules from the DISC-5 have also undergone translations into other languages and are currently in use in international studies. Of course, no RBI can substitute for thoughtful clinical practice, and the developers of the DISC have been clear that its use is solely adjunctive and facilitative, and not diagnostically definitive when applied in clinical settings (pwf1@columbia.edu [for information, copies, translations]; https://telesage.com/netdisc-5 [current computerized version]).

The Children's Interview for Psychiatric Syndromes (ChIPS) is a highly structured interview that was designed for use with lay interviewers to screen for current psychiatric disorders. The authors recommend that interviewers have at least a bachelor's degree in a field associated with mental health (e.g., psychology, social work, and psychiatric nursing). The first version of the ChIPS was specifically designed for interviewing children ages 6 to 12 years (unlike the DISC, which is not given to children under age 9); for later versions the age range was extended to include adolescents. Development of the parallel parent version (P-ChIPS) followed the child version. For each diagnosis, "cardinal" symptoms—those that are most frequently endorsed by youth who may have a particular disorder—are assessed first and, if not endorsed, the interviewer skips to the next diagnosis, making the interview briefer to administer than the DISC. The interview is scored by the interviewer using a scoring booklet that provides rules for scoring DSM diagnoses. The ChIPS has not been updated to DSM-5, but given the few changes in the diagnostic criteria, it should still be considered for use (https://www.appi.org/chips-childrens_interview_for_psychiatric_syndromes).

The Development and Well Being Assessment (DAWBA), which is widely used throughout Europe, although less so in the United States, assesses current diagnoses (the exact time frame varies by diagnosis) and is DSM-5 and ICD-10 compatible. The DAWBA was designed to provide a shorter alternative to typical diagnostic interviews by including many "skips" and screening questions. It also makes use of a companion screening questionnaire, the Strengths and Difficulties Questionnaire (SDQ). The DAWBA employs a two-part procedure beginning with an RBI comprising both closed-ended, precisely specified questions (answered "yes" or "no" or using a choice of two to three relevant options) as well as open-ended questions (to which the answers are typed verbatim into an open text field by the interviewer or, in a self-administered version, directly by the respondent). The open-ended questions obtain supplementary information about the symptoms and accompanying functional impairment. Thus, like the DISC, and the CHiPS, the DAWBA does not require much training to administer. There are parent and youth versions and a teacher questionnaire. When the interviews and questionnaires are completed, all information is forwarded to a clinical rater who has been trained by the authors of the DAWBA. This clinician reviews and assigns diagnoses based on the transcripts of the interviewer notes and answers to the structured questions from all available informants (usually parent and child, and sometimes the teacher). Preliminary scoring yields “likelihood” estimates, and provisional diagnosis is done by computer. The scoring rules used for the DAWBA have not been made available for review. The DAWBA and the SDQ have been translated into many languages (https://www.dawba.info/).

Kiddie Schedule for Affective Disorders and Schizophrenia—Computerized version (KSADS-COMP) is the newest version of the popular KSADS, the most widely used IBI (see below) and comprises three web-based versions—clinician administered (an IBI described below), and self-administered youth and parent versions (all RBIs). All KSADS-COMP versions follow the same structure as the most recent noncomputerized K-SADS, beginning with an introductory module, followed by a screening interview and then supplementary modules for diagnoses identified by the screening interview as being probable. KSADS-COMP youth and parent version contain the same structure, probes (one or two per symptom), response options, scoring, and branching options as the clinician version The KSADS-COMP parent and youth version differ significantly from all earlier versions of the KSADS, in which all probes were “suggested,” relying on the clinician to decide how to elicit information and to apply clinical judgment to decide when a symptom was present; in these earlier versions it was unclear after the fact how the particular probes included were selected Also, in the KSADS-COMP, a common frequency metric is used to rate presence of current (last two week) symptoms. (The parent version is text based, where the parent reads the probes, while the youth version includes an option to view videos of an interviewer reading the probes, instead of reading the probes themselves). Unfortunately, none of the three KSADS-COMP versions have been compared to the standard clinician-administered K-SADS, nor is such a comparison planned; results from ongoing research in community samples suggests that the RBI versions may overdiagnose some disorders (e.g., bipolar disorder, obsessive compulsive disorder) (https://www.ksadslogin.net/ksads-comp/aboutus.aspx).

The Flexible Interview for ICD-11 (FLII-11-Epidemiology) will soon be released from the World Health Organization. It was prepared by an international team and was specifically designed for administration by trained lay interviewers for use in international settings to assess the more common psychiatric disorders specified in the ICD-11. The impetus behind developing the FLII-11 was to make widely available a free instrument that could be used in large national studies that would find clinical utility in many settings. A downward extension of this interview for adolescents is being prepared and should be available in 2023.

Interviewer-Based Interviews. Various IBIs, developed to meet different research needs, are finding adjunctive use in clinical settings. These include the Schedule for Affective Disorders and Schizophrenia for Children (K-SADS) as mentioned above; the Anxiety Disorders Interview Schedule for Children (ADIS-C); the MINI International Neuropsychiatric Interview for Children and Adolescents (MINI-KID); the Child and Adolescent Psychiatric Assessment (CAPA); and a youth version of the Structured Clinical Interview for DSM-5 (Kid-SCID), a widely used adult measure, is in development, as is a youth version of the Structured Clinical Interview for ICD-11 (SCII-11). Finally, the Diagnostic Interview for Anxiety, Mood and Obsessive Compulsive and Related Neuropsychiatric Disorders—Child and Adolescent Version (DIAMOND-KID), which was initially developed for use in clinical settings, is finding use in research. As would be done in a typical clinical evaluation, most of these interviews begin with some sort of introductory module during which information about the child’s presenting problem(s) and a short clinical history are obtained, along with demographic information and information about current functioning which can be used to set the context for further inquiry. The length and content of this varies widely between instruments. With the exception of the SCII-11, which is keyed to ICD-11 diagnoses, all have been updated for DSM-5 and most can be used to assess ICD-11 diagnostic criteria. For each of the existing measures, a literature is available that defies summary here. Following are some brief comments about the currently available IBIs.

The K-SADS, originally developed for use in studies of child/adolescent depression was based on the SADS, an adult research instrument, and was the first widely used IBI for children and adolescents. Unlike the SADS, the K-SADS has kept pace with changes to the DSM. There are a number of different versions of the K-SADS, reflecting the modification of this measure by researchers at different sites with differing specific interests and assessment philosophies. Most assess current and lifetime diagnoses. Some versions incorporate severity scales for the criteria assessed, allowing their use in examining change, whereas others use more categorical scoring. With the exception of the KSADS-COMP parent and youth versions (which should be considered an IBI), all versions of the K-SADS contain probes that are “suggested,” but there are no questions that must be asked, because all versions of the K-SADS assume that the interviewer has been clinically trained and is experienced in assessing youth psychopathology. In the KSADS-COMP, clinician version, the clinician is also expected to use clinical judgment when asking or adapting questions and making ratings. Nonetheless, many research studies use trained research assistants to administer the KSADS interview, a practice which some have criticized. Following an overview (and, for the most recent KSADS-PL, a screening module), the interviewer proceeds through a series of modules to assess different diagnoses. For most of the K-SADS versions, the same person interviews both the parent and the child and, when necessary, works to resolve differences. The authors of the KSADS have recommended that for younger children the parent be interviewed first, whereas for adolescents, the recommendation is to interview the youth first; in practice, however, many have found that it makes more clinical sense to interview the parent first, regardless of the young person's age. Consensus ratings for each diagnostic criterion are made, based on the interviewer's clinical judgment using information from both informants and from any other source (e.g., clinical records). Diagnoses are then assigned by the interviewer using a series of score sheets; for the KSADS-COMP, the computer yields a diagnostic report using the clinician ratings. An early childhood version (K-SADS-EC) (parent informant only) has been prepared and used in studies of preschool depression (https://www.pediatricbipolar.pitt.edu/resources/instruments [for traditional KSADS]; https://www.ksadslogin.net/ksads-comp/aboutus.aspx [for KSADS-COMP]).

The ADIS-C, derived from the A-DIS, an adult interview, was originally developed for use in studies of childhood anxiety. The time frame for inquiry is current and lifetime; the interview provides extensive coverage of anxiety disorders and is particularly strong in this area, with less extensive coverage of other symptom areas. "Thermometers" are used to obtain severity, fear/avoidance, distress, and interference information and a clinician severity rating is made for each diagnosis (which makes possible tracking symptom change). The ADIS-C is designed to be administered by a clinician with experience in assessing child psychopathology. Like the K-SADS, the ADIS-C relies on a reconciliation procedure to sort out disagreements between parent and youth and the scoring is done by the clinician administering the interview, rather than by computer algorithm (https://global.oup.com/academic/product/anxiety-and-related-disorders-interview-schedule-for-dsm-5-child-and-parent-version-9780197621950?lang=en&cc=us).

The MINI-KID is a youth version of the MINI, a widely used research interview for adults, and was designed to quickly assess the presence of current and past psychiatric disorders of youth. Like the MINI, the MINI-KID incorporates a branching structure with each diagnostic section containing screening questions, which if not endorsed, allows the interviewer to skip the rest of the section. Unlike the administration procedure for all of the other diagnostic interviews for youth, parents and children are typically interviewed together, with question directed to the child and the parent asked to speak up if the information the child provides is not accurate. Discrepancies between informants are addressed by the clinician interviewer during the interview. For adolescents, sometimes only the adolescent is interviewed, depending on setting and user choice. There is a separate parent version available as well. The authors also have a “MINI Kid Screen” that comprises all the screening questions that can be used to screen for probable disorders prior to using the whole interview. Unlike the other IBSs in this section, the MINI-KID does not include an introductory module to set the stage for the rest of the diagnostic inquiry. Of all the IBIs, the MINI-KID takes the least time to administer (the authors estimate half an hour), due to the many skips and the efficiency of combining parent/youth interviews; however, some have questioned whether the screening questions are sensitive enough for some disorders. Diagnostic criteria are documented within each of the disorder sections and on a summary sheet by the clinician administering the interview (https://harmresearch.org/product/mini-international-neuropsychiatric-interview-mini-kid-kid-parent-version-7-0-2-10/).

The CAPA is a very comprehensive measure that, in addition to psychiatric symptomatology and impairment, covers family, environmental, and psychosocial problems, life events, the effect of the child’s problems on the family, and mental health service use. The time period assessed is last three months. Unlike the other interviews, the CAPA is not organized into obvious diagnostic modules. The CAPA contains a number of questions that should be asked exactly as written, with follow-up questions that are less specified. Unlike the K-SADS, the CAPA was specifically designed for administration by non-clinicians who undergo extensive training in how to administer the interview. This is accomplished by providing detailed definitions and rules that govern the assessment of reported phenomena and determination of whether they should be rated as symptoms. Thus, the onus is on the interviewer to assure that the questions are understood and the information provided is relevant. A clinically experienced supervisor reviews each CAPA interview before final ratings are made. Young Adult (YAPA) and Preschool Versions (PAPA) of the instrument are available. Like the DISC, the CAPA is scored according to well-specified computer algorithms. The CAPA has recently been computerized, easing administration and substantially reducing data entry costs. Training on the instrument typically takes 4 days (https://devepi.duhs.duke.edu/measures/the-child-and-adolescent-psychiatric-assessment-capa/).

The Diagnostic Interview for Anxiety, Mood and Obsessive Compulsive and Related Neuropsychiatric Disorders—Child and Adolescent Version (DIAMOND-KID), derived from an adult instrument (DIAMOND), was recently developed (post publication of the DSM-5) and is designed to address Anxiety, Obsessive-Compulsive, and related disorders more comprehensively than other currently available diagnostic interviews. The timeframe of inquiry is the past month, except when DSM-5 requires a longer timeframe (e.g., for bipolar disorder it is necessary to inquire about a lifetime history of mania). The DIAMOND-KID also includes some items that are rated based on observation of the youth or on the clinician's synthesis of all available information about the child. Like the MINI-KID, questions are directed to the child (if the parent is present) or the child is interviewed alone—there is no corresponding parent interview, although it is flexible enough that the clinician can decide how best to administer it. The DIAMOND-KID adheres closely to what a clinician would ask or probe in a comprehensive clinical evaluation. Handily, the interview includes information about differential diagnoses, common associated features, and specifiers for many diagnoses, which help to improve accuracy. This interview can be downloaded at no cost (https://giving.hartfordhospital.org/diamond/) and training costs are minimal.

Rating Scales

A large repertoire of questionnaires and rating scales have been developed to assess symptomatology and various aspects of behavior and adaptive functioning. Different measures have been designed for completion by parents, teachers, and/or children. Some of these questionnaires/scales include a broad range of symptoms (“omnibus” measures) while others focus on a more specific area (e.g., depression and anxiety). The development of each scale ideally involves testing its psychometric properties, that is, the functioning of the scale with respect to its reliability and validity as well as administering it to large and diverse samples to determine norms and clinically relevant cutoffs.

A number of specific aspects of scale functioning must be considered in selecting a scale in practice or research. Again, a basic issue is the nature of the intended use, that is, to aid in clinical assessment, treatment or planning or to address a research question or clinic/agency purpose (e.g., describe patients being treated or quality improvement). Intended use determines which domains of symptomatology and functioning must be covered and is tied to the nature of the sample or population with which it will be used. For example, the major scale requirements may vary for studies or clinical settings that assess clinical patients receiving an intervention designed to change symptom occurrence over time in contrast to studies estimating community population in which the prevalence of a disorder(s) would be relatively stable or else likely to change in response to an imposed condition (e.g., intervention) or the changing developmental stage of a cohort tracked over time. If one wants to implement a measure to track symptom change, which could be part of an effort to guide treatment and implement “measurement-based” care, it is also important to consider the timeframe for symptom assessment. In considering which scale to use for a particular purpose, the psychometric characteristics of various scales should be compared and factored into a decision, together with specific characteristics of the children or adolescents to be assessed. One obvious example is age. Given that developmental stage and not solely chronologic age determines the young person’s capacity to abstract at the level required by the particular scale’s questions, the appropriateness of such questions to the youngster’s activities and opportunities are all factors very important to accurate assessment. The young person’s cultural context also may bear on symptom reporting for various reasons, such as acceptability of reporting certain types of symptoms, culture-specific theories of etiology, or subjects' expectations of what is normative in behavioral or emotional expression. For self-completion questionnaires, literacy and reading level of parents and youth who will be completing the measure is also an important factor to consider.

Thus, although a particular scale may appear to provide a convenient tool for clinical or research use, many features of its demonstrated functioning, of the young people themselves, and of their social contexts must be taken into account when choosing a measure. Similarly, the critical reader will want to consider such factors in interpreting findings from the research literature. As for the diagnostic interviews, there are many issues to be considered when deciding which measures to use and, indeed whether to introduce measures into clinical practice at all. These include how, when and where to administer them, storage, and, for self-completion measures particularly, a procedure which assures that the clinician/clinical staff is provided with information obtained. For symptom measures, it is helpful if, in addition to a total score, the clinician is given the measure itself to see which items were endorsed to get a fuller picture of the youth. Finally, there is the issue of cost, as many of these measures must be purchased, which can be prohibitively expensive in low resource settings.

Comprehensive (Omnibus) Rating Scales. Probably the most widely used comprehensive symptom rating scales are those that constitute the Achenbach System of Empirically Based Assessment (ASEBA) family of instruments (http://www.aseba.org). There are forms for school-aged children—the Child Behavior Checklist for Ages 6 to 18 (CBCL/6 to 18), the Teacher Report Form (TRF/6 to 18), and the Youth Self Report (YSR/11 to 18); forms for younger children —the Child Behavior Checklist for Ages 1½–5 (CBCL/1½–5) and the Caretaker-Teacher Report Form (C-TRF); as well as forms for young and older adults to report on themselves. The ASEBA forms average 99 to 120 items and generate several syndrome scales. In addition, there are clinician-completed forms, including the Direct Observation

Form (DOF), which is completed after observing classroom behavior. Important features of this system of measures include its empirical development and the large population sample on which it was normed, as well as testing on large samples of clinically referred children. The availability of age-based and gender-based norms provides a convenient way to screen for overall levels of symptomatology, and when scored, the CBCL yields a profile of problem areas and competencies. The CBCL is stable over relatively brief intervals (i.e., good test–retest reliability) but also reflects changes resulting from treatment. The CBCL, TRF, and YSR have been widely used in epidemiologic and clinical research, in many clinical settings and in translated forms in numerous countries. These measures can be a useful clinical screening tool, as well as an efficient way for clinics to gather uniform information for characterizing the populations served as well as changes in those groups over time. Each of these measures includes DSM-oriented subscales for common youth diagnoses. Computerized data entry and scoring have greatly eased the use of the ASEBA measures and allow for comparisons of reports across informants (www.aseba.org).

The Behavior Assessment System for Children (BASC-3) is another widely used assessment system for evaluating aspects of behavior and personality in children and adolescents aged 2 to 21 years. It consists of parent and teacher rating forms, a Structured Developmental History form and a Student Observation System (for rating classroom behavior), and, for youngsters 8 to 21, a Self-Report of Personality (for thoughts and feelings). The parent and teacher measures have forms appropriate for ages 2 to 5 years, 6 to 11 years, and 12 to 21 years (the latter also has a youth form); each form has between 139 and 175 questions. A distinctive feature of the BASC is its emphasis on *positive* aspects of the child's adjustment, in addition to rating symptoms and problem behaviors. An additional feature of this system is its coverage of problems related to school functioning, such as difficulties in social or study skills, and it has built-in validity checks. Norms have been established for children by age, gender, and clinical status. This system has been designed for application in clinical, educational, research, and program evaluation contexts. Use and interpretation of the BASC are eased by the availability of computer software that generates profiles and allows consideration of different informants' viewpoints (https://www.pearsonassessments.com/store/).

The Conners Rating Scales are another family of instruments that are widely used in research and clinical settings. These include short and long forms of scales for parent administration CPRS-RS, CPRS-R-L, teacher administration (CTRS-R-S, CTRS-R-L), and self-report (CASS-S, CASS-L). These scales collect information on child oppositional behavior, cognitive difficulties, hyperactivity–impulsivity, anxiety and shyness, perfectionism, social problems, and psychosomatic complaints. The Conners scales have been developed and tested on samples of children and youth 3 to 17 years of age, for parent and teacher forms, and 12 to 17 years on the adolescent forms. These measures have shown excellent psychometric properties, and norms are available, as is computer software to aid in administration and scoring. The Conners scales have long been the standard instruments for the assessment of ADHD in children and adolescents, and their use for ADHD and Disruptive behaviors is described below (https://pearson.my.site.com/usclinical/s/article/Conners-3-Forms).

In contrast to the rather lengthy omnibus scales described above, the Strengths and Difficulties Questionnaire (SDQ) has been gaining in popularity in research, is very brief and is made freely available. The SDQ was designed to be used as a short screen to identify children (ages 2 to 17 years) with behavioral problems. A drawback from clinical use is that it does not cover any specific area in depth. The SDQ comprises 5 subscales (emotional symptoms, conduct problems, hyperactivity/inattention, peer relationship problems, and prosocial behaviors), for a total of 25 items: it has cross informant forms (parent, teacher, and self) and has been translated into over 75 languages Versions that include additional questions about "impact" and questions about given interventions are also available (www.sdqinfo.org).

DSM-5 also includes the "Parent/Guardian-Rated Level 1 Cross Cutting Symptom Measure—Child Age 6–17" which some clinical settings have found useful. This measure was created to help clinicians identify diagnostic domains that might not have been considered in a typical unstructured clinical assessment but may be important for a particular youth. The measure was found to be clinically useful and have good reliability in the DSM-5 field trials. A child rated version (ages 11 to 17) is also available (www.psychiatry.org/dsm5).

Other omnibus scales, which are available but have found less use in recent years include the Revised Behavior Problem Checklist (RBPC), the Louisville Behavior Checklist (LBC), and the Personality Inventory for Children (PIC). The RBPC focuses on symptoms of conduct disorder, socialized aggression, attention problems and immaturity, anxiety and withdrawal, with auxiliary scales for psychotic behavior and motor tension-excess. It was designed for use by parents and teachers of children and youth ages 5 to 17 years. Although generated using factor-analytic studies of clinical samples, it has also been normed on nonreferred children and youth. The LBC and the PIC are both comprehensive rating scales for parent report that do not have corresponding versions for other informants. The LBC consists of 19 scales that cover a wide range of behaviors and symptomatology. The PIC was developed on the model of the Minnesota Multiphasic Personality Inventory (MMPI) and also comprises a variety of component scales.

Disorder-Related (Domain Specific) Scales. Each of the scales described above was designed to collect information across a range of symptoms and competencies. More narrowly focused symptom rating scales have been developed to permit a more detailed quantitative assessment of specific symptom realms. These latter scales may be useful in quantifying the presenting severity of certain symptoms to establish a baseline against which response to a therapeutic intervention can be compared. A number of these scales are self-report measures. These have the advantage of providing an opportunity for the child to report on symptoms that might be difficult to conceptualize or verbalize. Sometimes parents or children (especially adolescents) are initially more willing to report an area of difficulty in the seemingly more anonymous context of a questionnaire than in a face-to-face interview. However, self-reports also carry the risk of the child misunderstanding questions or feeling compelled to provide socially desirable responses rather than acknowledge behaviors and feelings that the child believes might meet with disapproval. Fundamentally, the focused symptom approach may also ignore important interactions across domains of psychopathology, because of the focus on one particular area of symptomatology. With these potential limitations in mind, child self-report measures can provide useful adjunctive information in clinical and research settings.

SCALES FOR ASSESSING INTERNALIZING SYMPTOMATOLOGY—DEPRESSION. The Revised Child Anxiety and Depression Scale (RCADS, RCADS-25), is a self-completed measure suitable for screening and assessing *depression and anxiety* in youth ages 8 to 18, which has found wide use in research and more recently in clinical settings. The RCADS has good psychometric properties and was recently selected as a “core measure” for inclusion by the National Institute of Mental Health and the Wellcome foundation in their funded studies of youth. There are parallel youth and parent/caretaker forms. Each symptom item is rated on a four-point scale (“never” to ‘always”) and there are six subscales (major depression, generalized anxiety, social anxiety, separation anxiety, panic disorder, obsessive-compulsive disorder). The RCADS has been translated into many languages and is free to use (https://www.childfirst.ucla.edu/resources/).

The Patient Health Questionnaire (PHQ-9), another “core measure” selected by NIMH and Wellcome, includes nine items, corresponding to the nine DSM-5 criteria for Major Depression. A short two-item form is also available. Each item is rated on a frequency scale for the past 2 weeks. The PHQ-9 has found wide use for adults in clinical and research settings, with some use with adolescents, down to age 12. There is no corresponding parent/caretaker form. This free-of-charge measure can be obtained from many websites.

The Beck Depression Inventory (BDI) is a widely used scale for depressive symptoms in cognitive, behavioral, affective, and somatic domains. It has found wide use with adolescents. Because it is an "adult" measure, there is no corresponding parent version. The BDI was originally developed to measure the severity of depressive symptoms in patients who had been diagnosed with depression; it is also used to screen patients to identify depression and to monitor treatment outcomes. The BDI has been widely studied and used in clinical and nonclinical populations, with generally good psychometric properties. As with other scales, a fine-grained examination of the literature shows specific areas in which it falls short of ideal; for example, different cut-points are needed, depending on the population (inpatients vs. outpatients; male vs. female). Unlike the earlier version of the BDI, which did not provide complete coverage of the DSM depression criteria, the newest version, BDI-II, covers all the depression symptom criteria in the DSM system and extends the time frame of inquiry to 2 weeks, again to reflect the DSM duration requirements for Major Depressive Episode. Nevertheless, varying degrees of stability that are inherent to psychopathology in adolescence must also be kept in mind in the overall determination of the functioning of any scale. Generally speaking, positive results from various psychometric studies, ease of use, scoring and interpretation have made the BDI an attractive instrument in both clinical and research contexts (https://www.pearsonassessments.com/store/).

The Children's Depression Inventory (CDI) is a self-report measure for assessing symptoms of depression in children 7 to 17 years of age. It shares a conceptual basis with the BDI and comprises five factors: dysphoric mood, acting out, loss of personal and social interest, self-deprecation, and vegetative symptoms. As with many measures of child psychopathology, various psychometric properties vary by characteristics of the sample used, especially patient versus community status, gender, and age. As noted for the BDI, participant characteristics play important roles in interpreting psychometric results because, for example, the capacity to conceptualize and report on symptoms improves with age. Hence, scales reaching into the younger school-aged years are likely to show more variability in assessments of reliability and in examinations of agreement between child and adult informants. Levels of agreement with other measures related to depressive psychopathology and its known correlates have provided support for the validity of the CDI. It has been widely used across a range of populations; thus, as with the BDI, the availability of considerable information relevant to its performance with different groups of children and youth makes it attractive to those considering it for use in various research and clinical populations. Parent and teacher informant forms are available. Many useful results have emerged from studies using the CDI, further adding to its attractiveness as a measure of depressive symptomatology. One criticism of the scale is that adolescents may find it too “babyish” (https://storefront.mhs.com/collections/).

The Center for Epidemiologic Studies Depression Scale (CES-D), was developed first as a rating scale for depressive symptoms in epidemiologic studies of adults, but it has also been widely used with adolescents, and a modification (CES-DC) was developed specifically for use with younger individuals. Both are freely available from many websites. There is no corresponding parent measure. Psychometrically, the CES-DC functions sufficiently well in some domains for adolescents but, overall, does not hold up well for children. Both instruments are brief and easy to use, and, particularly in adolescents, some aspects of reliability and validity meet performance standards. However, for both measures, problems with discriminant validity pose limitations, suggesting that they may be most appropriately considered as screening tools for general psychopathology in adolescent populations. An alternative version of the scale, Center for Epidemiologic Studies Depression Scale Revised (CESD-R-20), adheres more closely to the DSM diagnostic criteria for Major depression, compared to the original scale, and includes questions about suicide ideation (not assessed in the original scale) as well as an additional frequency rating (whether present nearly every day for 2 weeks).

The Mood and Feelings Questionnaire (MFQ) is another freely available brief self-report measure designed to screen for and assess core depressive symptoms for children and adolescents. Originally designed for use in epidemiologic studies, the MFQ has also found use in clinical settings and screening programs. There are long (32-

item) and short (13-item) versions of the scale, and parallel parent and youth reports. Although these questionnaires have demonstrated good psychometric properties and discrimination for depression appears better than for other self-report measures, they are not as widely used as the other scales (https://psychiatry.duke.edu/research/research-programs-areas/assessment-intervention/developmental-epidemiology-instruments-0).

The Quick Inventory of Depressive Symptomatology (QIDS) and QIDS-A (a version for adolescents that includes an extra item assessing irritability) are short forms of the Inventory of Depressive Symptoms (IDS) and are confined to the symptoms of Major Depressive Episode. In addition to a self-completed questionnaire, there is a corresponding clinician rated version, as well as a structured interview guide. The QIDS has strong psychometric properties and is useful for tracking treatment response. These tools are free and available from many websites.

Two related scales, the Reynolds Adolescent Depression Scale (RADS, RADS-2) (for ages 11 to 20) and the Reynolds Child Depression Scale (RCDS, RCDS-2) (for ages 7 to 13), are widely used measures to assess a wide range of symptoms associated with depressive disorder. Symptoms are rated on a 4-point Likert-type response scale that yields scores on four subscales (dysphoric mood, anhedonia/negative affect, negative self-evaluation, and somatic complaints). Both the RADS and the RCDS function very well in terms of reliability (both internal consistency and test–retest). The validity of the RADS is supported by relationships with other measures of depressive symptomatology and related constructs. It has been used with diverse populations, providing a broad base of evidence for its functioning, as well as normative comparison data. The strong psychometrics, basis in the highly specified symptomatology of the DSM system, and the linkage of the two scales for use in longitudinal studies or across a broad age range in a single study are advantageous features of these measures. The RADS and RCDS are often used as screening measures to identify depressed youth (there is no corresponding parent measure), and there is some evidence that these measures may be sensitive to clinical change, so they hold promise for evaluating treatment outcomes (https://www.parinc.com/Products/).

The Hamilton Rating Scale for Depression (HRDS), another freely available measure, differs from the aforementioned measures in being a clinician-rated scale. It is the most commonly used clinician rating scale for depression. Developed for assessing depressive symptoms in adults, the HRDS has also been used in studies of adolescents. The HRDS was initially developed to measure the severity of symptoms in patients who had a depressive illness and was widely used in psychopharmacological and other treatment studies evaluating outcomes of different treatments for depression. The original scale had 21 items, of which only the first 17 were scored; there are alternative versions with 23 items and also versions with fewer items. Not all of the versions have been psychometrically evaluated. Although internal consistency and inter-rater reliabilities have generally yielded acceptable to excellent results, specific training in its administration and the use of a structured or semi-structured protocol for administering the HDRS improves the psychometric properties. The validity of the HRSD has not been as convincingly demonstrated in adolescent populations as for adults. The main application has been in treatment outcome studies, in which findings have supported its sensitivity to the effects of certain psychopharmacologic agents, as well as to other specific therapeutic modalities. The HRDS is free for download from many websites.

The Children's Depression Rating Scale-Revised (CDRS, CDRS-R) is a clinician-rated symptom inventory related to the HRDS but designed for the assessment of school-aged children. It uses clinician expertise by including their ratings of behavior observed during the interview and by having clinicians generate scores based on information from each parent and child considered alone, as well as a combined score that integrates information from both informants. Psychometrically, aspects of reliability have ranged from adequate to excellent, depending on the study and type of reliability considered. There is some support for validity, and the CDRS has found substantial use in clinical research generally and treatment outcome studies specifically. Overall, the unique features of the CDRS, clinician rating, and use of multiple informants have made it attractive for studies conducted in settings in which the use of clinicians is feasible and their skills in eliciting and integrating information are advantageous for the study design (https://www.wpspublish.com/cdrs-r-childrens-depression-rating-scale-revised).

SCALES FOR ASSESSING INTERNALIZING SYMPTOMATOLOGY—ANXIETY. The Revised Child Anxiety and Depression Scale (RCADS, RCADS-25), a self-completed measure assessing anxiety and depression in youth ages 8 to 18, was described above.

The Screen for Child Anxiety-Related Emotional Disorders (SCARED) is a self-rated scale developed for children and adolescents ages 9 through 19 years, with a parallel form to be completed by parents. It maps onto the criteria for DSM-IV anxiety disorders of five types: somatic/panic, generalized anxiety disorder, separation anxiety disorder, social phobia, and school phobia. The overall scale and subscales show reliabilities comparable to those of other well-functioning scales, and there is evidence for convergent and discriminant validity of the SCARED with respect to other assessment measures and types of psychopathology. The SCARED has been shown to be sensitive to treatment effects. There are long (41-item) and short (5-item) versions of the scale, and the instrument has been translated into many languages. The SCARED is available at no cost at www.pediatricbipolar.pitt.edu under resources/instruments.

The Multidimensional Anxiety Scale for Children (MASC) is an empirically derived self-rated scale for children and adolescents that comprises the four major factors of anxiety, namely physical symptoms, social anxiety, harm avoidance, and separation anxiety. With respect to scale construction, the MASC maps onto the diagnosis of generalized anxiety disorder and individual factors capture the specific diagnoses of separation anxiety disorder and social phobia. With respect to psychometrics, various types of reliability and validity have been moderate to excellent. It has attractive structural features in capturing and distinguishing specific types of anxiety symptoms, and some results indicate that it distinguishes the constructs of anxiety and depressive symptoms in young people as well as being sensitive to treatment effects. The MASC has been translated into over 15 languages. The most recent form, MASC-2, has a corresponding parent version (https://storefront.mhs.com/collections/masc-2).

The Generalized Anxiety Disorder Scale (GAD-7) is another selected measure included in NIMH and Wellcome funded studies of youth. This self-completed questionnaire comprises seven items (with a 2-item short form) addressing GAD symptoms and has found use with adults and some use with youth (down to age 12). As with the PHQ, mentioned above, there is no parallel parent/caretaker form. The GAD-7 (and GAD-2) is free of charge and can be downloaded from many websites.

The Revised Children's Manifest Anxiety Scale (RCMAS), a downward extension of the adult Manifest Anxiety Scale, was developed to assess trait anxiety in school-aged children, although it has also been used with adolescents. Unlike many of the other scales, it does not have a parent informant version. The RCMAS has three component subscales: physiologic, worry/oversensitivity, and fear/concentration. It has been in use longer than the MASC and the SCARED, and thus experience has yielded a number of studies that document the psychometric properties of the RCMAS. Concurrent validity has been supported through comparisons with other measures of anxiety, although examination of discriminant validity has found that ADHD symptomatology may be rated for those who are primarily anxious. The many studies using the RCMAS have contributed to the understanding of assessment issues in anxiety disorders among the young and the role of anxiety in children and youth from various ethnic/cultural groups and diverse stressful social contexts. Some construct and other methodologic limitations have been noted which may have their origin in the inception of the RCMAS prior to the newer, DSM-linked measures (https://www.wpspublish.com/rcmas-2-revised-childrens-manifest-anxiety-scale-second-edition).

The State-Trait Anxiety Inventory for Children (STAIC), also based on an adult instrument, is another youth-only self-completed measure. The STAIC comprises two subscales, each of 20 items; one quantifies “state” with the other quantifying “trait” anxiety. It thus distinguishes between a general proneness to anxious behavior and anxiety as a fleeting emotional state. The subscales can be used independently. The STAIC is designed to be used with upper elementary or junior high school aged children youth but can be administered verbally to younger children. The STAIC has demonstrated acceptable psychometric properties and has somewhat better specificity than sensitivity. It has been shown to be sensitive to change and useful in assessing response to stress (https://www.mindgarden.com/146-state-trait-anxiety-inventory-for-children).

The Pediatric Anxiety Rating Scale (PARS) is another clinician rating scale that is freely available. The PARS, modeled on the Children’s Yale-Brown Obsessive Compulsive Scale (CY-BOCS), was developed by the NIMH funded Research Units on Pediatric Psychopharmacology, for a study on child anxiety to target symptoms that the researchers thought were not adequately covered by the HARS. In administering the PARS, the clinician first reviews the child’s specific symptoms of anxiety and then makes severity ratings on seven dimensions using a six-point scale. The psychometrics of the PARS are good and the scale is useful for tracking treatment response. However, administration can be lengthy. The scale can be downloaded for free.

The Hamilton Anxiety Rating Scale (HARS) focuses on anxiety symptoms and, like its depressive symptom counterpart, the HDRS, is a freely available clinician-rated scale, which has been used with adolescents. The HARS is generally administered to both adolescent and parent to yield an overall rating. It covers both psychological and somatic components of anxiety (focusing heavily on the latter), with psychological symptoms showing better internal consistency than somatic ones. Other aspects of reliability are moderate to excellent, depending on the type of reliability examined, while validity is not strongly supported. The use of clinicians for the assessment and the use of multiple informants are potentially advantageous features, although more study is needed to elucidate the psychometric performance of the HARS and its utility as a treatment outcome measure. The HARS can be downloaded from many websites.

SCALES FOR ASSESSING EXTERNALIZING SYMPTOMS—ATTENTION-DEFICIT/HYPERACTIVITY DISORDER WITH AND WITHOUT RELATED SYMPTOMS. The NICHQ Vanderbilt Assessment Scales, Parent and Teacher forms (VADPRS and VADTRS, respectively) are self-completed screening questionnaires that assess frequency of DSM ADHD, Oppositional Defiant Disorder and Conduct Disorders symptoms in the last 6 months on a 4-point scale ("never" to "very often"), has screening questions for Anxiety and Depression, and also questions concerning performance problems or impairment (55 items). Follow-up versions (26 items) designed for tracking change in ADHD symptoms (with a user-defined timeframe and potential side effects from medications/interventions are also available. These scales have good psychometric properties and have found wide use in clinical as well as research settings and are freely available. Although originally developed for children aged 6 to 12, it is possible to use these scales in older youth (https://www.nichq.org/sites/default/files/resource-file/NICHQ_Vanderbilt_Assessment_Scales.pdf and numerous other websites).

Several scales developed by C. Keith Conners and colleagues are commonly used to assess and monitor ADHD and other externalizing disorders. The Conners (third edition) has parent, teacher, and self-rated versions, all with good psychometric properties. There are long and short versions for each form, and each assesses symptoms of ADHD, Conduct Disorder and Oppositional Defiant Disorder, with each symptom being rated on a 4-point scale; in addition to symptom counts and scales, it also yields a Conners ADHD index and a Global Index. There is sophisticated computer software that aids in administration and scoring. The more recent Conners 4 is confined to ADHD and related problems (it does not include Conduct and Oppositional symptom assessments). Other commonly used Conners instruments include the Conners Abbreviated Symptom

Questionnaire, Hyperactivity Index (CASQ-HI), the Conners ADHD Index and Inattention/Overactivity with Aggression (IOWA) Conners Scale, and the Conners, Loney, and Milich (CLAM) Scale. The CASQ-HI is a brief (10 item) checklist of the 10 most "medication-sensitive" hyperactivity items from the longer Conners' scales. In addition to assessing treatment response, the CASQ-HI has often been used to screen for ADHD; however, it has been criticized as potentially missing children whose primary problem is inattention. The Conners ADHD Index addresses this possible weakness in identifying inattentive symptomatology in that the 12 items that comprise the index were derived to discriminate between children with ADHD and without ADHD. The IOWA Conners Scale has two subscales: Inattention/Overactivity (IO) and Oppositional Defiant (OD). For each subscale, items were selected to have the least overlap with the other scale. In practice, however, the scales correlated moderately in clinical samples. The CLAM Scale combines the CASQ with the IOWA Conners. All of these scales are brief, widely applied, have demonstrated good psychometric properties, and have been used to identify children in need of intervention and to track treatment response. In addition, Conners has developed scales for preschool children and for identification of adults who have ADHD (https://storefront.mhs.com/collections/clinical#adhd).

A second "family" of scales focusing primarily on ADHD has been developed by Swanson and colleagues, all of which are made freely available. The most widely used of these is the short version of the Swanson, Nolan, and Pelham (SNAP-IV) Rating Scale, which comprises a checklist of the DSM-III, DSM-III-R, and DSM-IV ADHD and ODD criteria rated on a 4-point scale and allows comparison between the different diagnostic formulations. The scale can be completed by either parent or teacher. The longer SNAP-IV contains items for other DSM diagnoses as well, and a more abbreviated version of the SNAP-IV contains only the ADHD items. The Strengths and Weaknesses of ADHD-symptoms and Normal-behavior (SWAN) Scale includes the same DSM ADHD symptom types as the SNAP-IV, but each is written so that it can be considered as an area of strength or weakness (e.g., the SNAP-IV "often is distracted by extraneous stimuli” appears as “ignores extraneous stimuli” on the SWAN). The parent or teacher is asked to consider each symptom as a dimension and rate the strengths or weaknesses of the child using a 7-point metric that compares how the child does in comparison to other children, ranging from “far below average” to “far above average. Finally, the Swanson, Kotkin, Agler, M-Flynn, and Pelham (SKAMP) rating scale was created to monitor the classroom behavior of a child, rather than DSM symptoms; it contains 10 items about typical target behaviors addressed by psychosocial interventions. The SKAMP is completed by the child’s teacher and is incorporated in the full teacher version of the SNAP-IV. The main disadvantage of the Swanson family of scales is the limited psychometric or normative data on their functioning. (These instruments are free and readily available for download from numerous websites.)

In addition to the Vanderbilt, Conners, and Swanson scales, there are a number of other brief symptom checklists keyed to the DSM criteria that can be used to assess ADHD and other related behaviors. These include the ADD-H Comprehensive Teacher Rating Scale (ACTeRS); the Attention Deficit Disorders Evaluation Scale (ADDES, home and school versions), the Yale Children’s Inventory (YCI), a parent rating scale designed for children with learning disabilities); the Vanderbilt AD/HD Diagnostic Teacher Rating Scale; the ADHD Rating Scale; and the ADHD Symptom Checklist.

OTHER SCALES FOR EXTERNALIZING SYMPTOMATOLOGY. The Eyberg Child Behavior Inventory (ECBI) is a parent-completed rating scale, with its teacher-completed companion, the Sutter–Eyberg Student Behavior Inventory (SESBI-R), was designed to assess a wide range of disruptive behavior symptoms in children aged 2 to 16 years. These easy-to-use scales have found wide use in treatment studies and in clinical settings and must be purchased. For each of the behaviors assessed (36 on the ECBI and 38 on the SESBI-R), the informant rates the frequency of the behavior on a 7-point scale (never to always) and then rates whether the behavior is “currently problematic.” Two scores are generated—the Intensity Score (based on the frequencies) and the Problem Score (calculated using ratings on how problematic each behavior is). Normative data for these scores are provided. The scale scores have good internal consistency for gender, ethnic, and age groups, and although they are not tied to DSM diagnoses, the ECBI has shown good discriminant and concurrent validity, strong temporal stability, and evidence of construct validity (https://www.parinc.com/products/pkey/97).

The Antisocial Process Screening Device (APSD) was designed to identify psychopathy and can be completed by either parents or teachers about children ages 6 to 13 years. This 20-item scale is based on Hare's Psychopathy Checklist-Revised. Items on the APSD address callousness, narcissism, and conduct problems that are related to poor impulse control. The scale has acceptable internal consistency, there is evidence for construct validity, and norms are available for the scale. Sensitivity and specificity have not yet been established, and there are no recommended "cut offs" for diagnosing antisocial psychopathology (https://www.wpspublish.com/apsd-antisocial-process-screening-device).

The Children's Aggression Scale (CAS), based on the Overt Aggression Scale (OAS) and the Buss–Durkee Hostility Index (BDHI), was developed with a specific focus on aggression, rather than a DSM diagnosis, as exhibited by youth ages 5 to 18 years. There are parallel parent and teacher versions (but no self-report version); the CAS has shown good psychometric properties and has been normed (https://www.parinc.com/Products/).

In addition, several other scales have been developed to monitor aggression and hostility. These include: The OAS, which is used widely in inpatient settings; modifications of the BDHI; the Vitiello Aggression Questionnaire (VAQ), which differentiates proactive from reactive aggression; and the Direct and Indirect Aggression Scale (DIAS). Unfortunately, normative data for most of these scales are not available for youth, although initial psychometric analyses look promising.

SCALES FOR OTHER SYMPTOM AREAS, IN BRIEF. For Autism spectrum disorders there are several good and widely used screening measures: the Social Communication Questionnaire (SCQ), the Autism Spectrum Screening questionnaire, the Childhood Autism Rating Scale, 2nd Edition (CARS 2) and, for very young children, the Modified Checklist for Autism in Toddlers (M-CHAT). The state-of-art diagnostic measures–the Autism Diagnostic Interview Revised (ADI-R) and the Autism Diagnostic Observation Schedule (ADOS-2)–are both clinician-administered and require specific training. For Obsessive Compulsive Disorder, the Leyton Obsessional Inventory–Child Version (LOI-CV) is useful as a screen and has good psychometric properties. The clinician administered Children's Yale-Brown Obsessive-Compulsive Scale CY-BOCS (adapted from an adult measure) is the most widely used research and clinical measure for tracking treatment change; there are also self- and parent-report versions. Widely used screening measures for Posttraumatic stress symptoms include the UCLA Post-traumatic Stress Disorder Reaction Index (UCLS-PTSD-RI) and the Children's Revised Impact of Event Scale (CRIES), both downloadable and free of charge. There are also many freely available screening measures for substance problems, including the CAGE, the Drug abuse screen test for Adolescents (DAST-A), and the Michigan Alcoholism Screening Test (MAST).

SCALES ASSESSING ADJUSTMENT AND IMPAIRMENT. Instruments also exist for assessing levels of adaptive functioning and impairment, globally or with respect to specific domains. The Children's Global Assessment Scale (CGAS) is an easy-to-use quantitative scale for the clinician's rating of overall impairment. The CGAS has good psychometric properties and has been translated into over 20 languages. A parent-completed version of the CGAS is also available. The Columbia Impairment Scale (CIS) and the Brief Impairment Scale (BIS) are both self-completed rating scales of impairment that tap four major areas of functioning: interpersonal relations, broad psychopathological domains, functioning in school or at a job, and use of leisure time with parent and youth (ages 9 and older) versions. The WHO Disability Assessment Schedule (WHO-DAS) was adapted for youth as part of the DSM-5 revision process. This scale includes parent-rated and youth-rated questionnaires as well as a clinician-rated component. The CGAS, CIS, BIS, and WHO-DAS are all free of charge.

The Vineland Adaptive Behavior Scales 3rd Edition (Vineland-3) provide a comprehensive age-normed framework for systematically recording and assessing the development of children and adults (multiple versions for birth to age 90) with respect to various realms of adaptive functioning. For youth, there are self-report, parent-report, and teacher rated forms. The Vineland has been widely used in both clinical and research settings.

Various structured and semi-structured formats for performing or recording portions of the child mental status examination have also been developed. Some, such as the child version of the Mini-Mental State Examination, contain specific standardized items for screening cognitive functions. Other instruments, such as the Mental Health Assessment Form, provide a format for organizing mental status data derived from a semi-structured clinical interview.

Limitations of Structured Measures in Clinical Assessment

Interviews and scales, such as those described previously, can, at times, be helpful adjuncts in clinical assessment if thoughtfully chosen and administered with sensitivity to their meaning in the overall process of the evaluation. For example, they can help to ensure a comprehensive review of symptoms or provide a standardized baseline measure of severity for later determination of intervention efficacy. They cannot, however, replace an individualized child psychiatric interview or be relied on as the sole basis for establishing diagnoses or planning treatment. Most standardized interview schedules focus on symptoms and behaviors, with little attention paid to coping mechanisms, situational context, and adaptive strengths that the clinical interview affords. Such factors may be as crucial to the clinical assessment and treatment planning as the presence or absence of a given pathognomonic symptom or categorical diagnosis. (Indeed, the limitations of standardized instruments in the clinical setting are acknowledged by the authors of many of these instruments, some of which require the user to seek permission from the authors and sign a license or complete a qualification form before being allowed to administer or order the instrument to ensure proper professional use. Some, like the DISC, require that the user agree that the interview not be used in place of thorough clinical evaluation in making treatment decisions.)

Another caveat in the clinical setting is to be wary of over-reliance or “reification” of a measure, especially with less experienced clinicians, who may assume a score on an inventory is more “valid” than their clinical observations, even though none of these measures should be considered as perfect. For example, a depressed child who has become withdrawn, has insomnia, and difficulty concentrating might not endorse many symptoms on a depression inventory, but that doesn’t mean the child isn’t depressed. The child’s clinician must take account of features such as the child’s affect, rate of speech, and reports of how the child is interacting with peers and family before concluding that depression is not present. Often the issue isn’t *whether* a standardized instrument might be used, but rather *how* it is used. For example, youngsters and their parents will sometimes more readily admit symptoms on a self-completed questionnaire than in a face-to-face interview. Similarly, self-completion forms can be clinically useful in giving a clinician a starting place with a noncommunicative patient. In such instances, it is useful to provide the questionnaire itself to the clinician rather than just a score, so that the clinician can review it with the patient or parent. When using any of the measures in a clinical setting, it is important to consider carefully the procedures for generating the most useful information from the measure and how best to share that information with the clinical team.

The researcher interested in selecting measures for a study protocol must carefully review the existing measures in the area of interest and consider the psychometric characteristics of potential measures as well as the appropriateness of the measures for the specific study sample and goals of the study. It is useful to begin by examining up-to-date critical reviews of these measures to evaluate the interviews/scales being considered and to actually test them out on volunteers, or if not available, with clinically savvy colleagues who can role play in developmentally and symptomatically authentic ways.

If the researcher is not experienced with biostatistics, it is highly recommended that the basic psychometric papers be reviewed by a statistician colleague. Combining information from these different perspectives will maximize the chances that the time and effort put into data collection will yield information that is interesting and ultimately useful to the fields of child psychopathology, treatment, psychosocial intervention, and ultimately prevention.

PSYCHOLOGICAL AND NEUROPSYCHOLOGICAL ASSESSMENT

Psychological tests of personality, intelligence and various neurocognitive and behavioral abilities can be a valuable tool in answering a specific referral question following an initial psychiatric evaluation described above. These tests provide a unique and more in-depth perspective on the child's functioning by generating data complementary to that obtained from history, observation, and interview. Combined with clinical interviews, psychological testing data may clarify relationships among various etiologic factors and/or may help direct the selection of appropriate intervention. Advantages of testing include identifying neuropsychological strengths and deficits, identifying learning styles, understanding underlying reasons for academic difficulty and being less influenced by certain reporting biases (e.g., social desirability, malingering) than self-report. Psychological testing also provides data that are more quantitative than the qualitative information provided by the child's history, presenting complaints, and clinical presentation.

The quantitative character of test findings is more important in the assessment of cognitive abilities than in personality assessment because the child's relative strengths and weaknesses in mental processing can be estimated only grossly from history and clinical observation. Such clinical estimates are also necessarily less accurate. The ability to discriminate meaningful differences between various domains of functioning helps clarify the particular pattern or syndrome evidenced by the child. The assessment of cognitive functioning also reveals cognitive impairments that may underlie or influence the psychological condition under investigation (e.g., whether poor social judgment in a child with conduct disorder also results from a nonverbal learning disability). Furthermore, the manner in which any cognitive impairments or strengths interact with the child’s psychological disorder can be delineated. These findings can be useful in helping students find success in school with appropriate levels of academic support and classroom accommodations. Findings from tests of personality identify important dynamics that affect the child’s clinical condition, which help inform clinical treatment recommendations for therapists, medication providers, and school counselors.

Referral for Psychometric Assessment

A referral for a psychometric assessment of the child is a request for a professional consultation to provide an opinion regarding the referral questions. The referral for psychological examination is analogous to that made to a neurologist or radiologist, who uses their assessment methods and particular expertise to contribute potentially valuable information that can be integrated into the psychiatric evaluation. For example, a referral may be made to understand underlying reasons for a teenager exhibiting sudden academic decline. Another example is a referral to understand whether attention and processing difficulties are best explained by an adolescent-onset mood disorder or a primary attention disorder dating to earlier in childhood. Referrals are, therefore, best worded in terms of the information that is needed (e.g., what is the current level of academic functioning relative to cognitive potential?), the issues to be resolved (e.g., intactness of reality testing, differentiating between potential diagnoses), or the decisions that must be made (e.g., psychiatric treatment recommendations, academic placement/accommodations), rather than requesting that specific tests be administered.

Less commonly, referral questions can be broad in scope. Requests of this nature may include a second opinion regarding the child’s condition or follow-up to previous neuropsychological testing. Regular follow-up of neuropsychological testing at fixed time intervals (e.g., every 3 years) may be indicated in medical conditions such as head injury/concussion or following neurosurgery or radiotherapy to the head for treatment of a malignancy. While it is best practice to state a specific referral question, referrals can be made for a general type of evaluation: psychological versus neuropsychological. A request for a *psychological* evaluation is commonly understood by the psychologist to mean assessment of personality, symptoms, intelligence, and achievement. In contrast, a request for a *neuropsychological* evaluation is assumed to mean a more comprehensive assessment of cognitive functioning, including intelligence, memory, complex mental processing, executive functioning (i.e., planning, organizing, time management), attention, language, visual perception, and motor functioning, with only a screening of social and emotional behavior.

Referrals for psychological examination should be made to professionals who are properly trained to use the appropriate instruments and to interpret the results. Just as psychiatrists may specialize in the treatment of adult, child, or geriatric patients or may develop a special expertise with certain disorders, psychologists also develop specialized skills in assessing certain groups of children or syndromes. Just as in medicine, board certification in clinical psychology or pediatric neuropsychology is one method for identifying psychologists with specialty qualifications. The American Psychological Association directory or various directories of certifying boards are useful references in the search for an appropriate examiner.

The primary purpose of neuropsychological evaluations is not to detect brain damage. Rather, comprehensive assessment of cognitive functioning and sensory-motor functioning permits the identification of deficits that cause academic, social, or developmental disabilities or that impede psychiatric treatment. Such assessments also identify the child’s areas of strength and weaknesses and help provide the basis for prescribing rehabilitative interventions that may be delivered as special education, occupational therapy, physical therapy, or vocational or cognitive rehabilitation. By parsing the psychological and cognitive impairments that contribute to the child’s functional disability, such assessments also help delineate the interaction between the child's psychological disorder and cognitive impairments. Although neuropsychologists are familiar with the cognitive sequelae of various neurologic conditions and can be particularly helpful in the assessment of children with neurologic disorders, any child requiring a detailed assessment of cognitive functioning is appropriate for referral.

Psychological Test Batteries

Table 35.1–7 contains a list of commonly used psychological measures for various domains of functioning. A comprehensive examination samples all of the domains, whereas a more focused evaluation selects a subset. In the most general sense, a battery of tests consists merely of a collection of tests to measure a variety of mental functions. There are loosely defined batteries that are routinely administered in psychological examinations. For example, the psychological battery for a child often includes the Wechsler Intelligence Scale for Children-V (WISC-V) or the Kaufman Assessment Battery for Children-III (K-ABC-III) as the measure of intelligence. In addition, there may be a measure of achievement in basic linguistic skills and math, such as the Test of Achievement from the Woodcock–Johnson Psychoeducational Battery—Fourth Edition (W/JPB-IV)—or the Wechsler Individual Achievement Test—Third Edition (WIAT-III). A test of visuomotor integration or visual construction, such as the Beery–Buktenica Test of Visual Motor Integration (VMI) or the Rey–Osterreith Complex Figure, is also usually administered. Finally, a variety of personality tests and behavior rating scales are used.

Some published test batteries consist of measures of various mental functions that have been developed together and can usually be combined into composite or factor scores. For infants and preschool children, psychometric instruments primarily focus upon development, including motor, sensory, perceptual, and language development and the development of conceptual reasoning. Comprehensive developmental quotients are derived from many of these instruments. The Bayley Scales of Infant and Toddler

Development 4 (Bayley-4) and the Mullen Scales of Early Learning are two notable examples. The Woodcock-Johnson Psychoeducational Battery-Fourth Edition (W/JPB-IV) and the NEPSY-2 are appropriate for school-aged children and examine a variety of smaller domains of functioning.

Personality Measures

Personality tests include both objective and projective assessment tools. For adolescents, the Minnesota Multiphasic Personality Inventory-Adolescent (MMPI-A), the Millon Adolescent Personality Inventory (MAPI) and the Millon Adolescent Clinical Inventory (MACI) are three well-known examples. These tests involve between 160 and 478 true–false self-report items and yield personality profiles based on scales of various psychological attributes such as emotional patterns, clinical symptoms, and apprehensions in teen life. Objective measures of personality for younger children are usually limited to behavior rating scales or structured reports by parents or caregivers. The Personality Inventory for Children—Second Edition (PIC-2) and the Behavior Assessment System for Children—Second Edition (BASC-2) are good examples of these measures.

For younger school-aged children, personality measures consist primarily of projective tests. Projective tests contrast with objective tests of personality in that projective tests use limited structure and ambiguous stimuli to which the child can respond in a virtually unlimited variety of ways. Perhaps the best-known example of a projective technique is the Rorschach Test. Other projective tests commonly used for the young, school-aged child include the Robert’s Thematic Apperception Test (RTAT) and the Children’s Apperception Test (CAT), which requires the child to compose a story in response to a picture depicting a scene that is suitable for children. A variety of tests administered to this age group require the child to draw, such as the Draw-A-Person (DAP) test, the House-Tree-Person (HTP) test, and the Kinetic Family Drawing (KFD). (Methods exist for scoring children’s drawings to assess cognitive and visual motor development, as well as affective content.) For the most part, the interpretation of responses to projective tests of personality is inferential; that is, the meaning is not self-evident in the response. The inferences are based on accumulated clinical experience reported in the literature, symbolic interpretation or analogous reasoning based on a theory (e.g., psychoanalytic theory), and, to a much lesser extent, empirically established norms. The notable exceptions are the scores derived from the RTAT and the Exner and Rorschach-Performance Assessment System (R-PAS) scoring systems for the Rorschach test, which have norms and have been extensively studied in empirical research.

Table 35.1–7.
Commonly Used Psychological and Neuropsychological Tests for Children and Adolescents

General Ability/Intelligence Tests	For Ages (years)
Differential Ability Scales, Second Edition (DAS-II)	2:6–17:11
Kaufman Assessment Battery for Children, 2nd ed. (KABC-2)	3:0–18:11
Stanford-Binet, Fifth Edition (SB-5)	2:0–89:11
Wechsler Preschool and Primary Scale of Intelligence, 4th ed. (WPPSI-IV)	2:6–7:7
Wechsler Intelligence Scale for Children, 5th ed. (WISC-V)	6:0–16:11
Wechsler Adult Intelligence Scale, 4th ed. (WAIS-IV)	16:0–90:11
Wechsler Abbreviated Scale of Intelligence 2nd ed. (WASI-II)	6:0–90:11
Woodcock–Johnson Tests of Cognitive Abilities, 4th ed. (WJ-IV)	2–90+ years
Achievement Test Batteries	
Kaufman Test of Educational Achievement, 3rd ed. (KTEA-3)	4:6–25:11
Peabody Individual Achievement Test—Revised (PIAT-R)	4:0–50:11
Wechsler Individual Achievement Test, 3rd ed. (WIAT-III)	4:0–50:11
Wide Range Achievement Test 4 (WRAT4)	5–94 years
Woodcock–Johnson Tests of Achievement, 4th ed. (WJ-IV)	2–90+ years
Neuropsychological Test Batteries	
Delis-Kaplan Executive Function System (DKEFS)	8–89 years
Halstead–Reitan Neuropsychological Test	5–8, 9–14, 15+

Batteries	years
Luria-Nebraska Neuropsychological Battery—Children's Revision	8–12 years
Luria-Nebraska Neuropsychological Battery (LNNB)	15+ years
NEPSY-II: A developmental neuropsychological assessment, 2nd ed.	3–16 years
Reitan-Indiana Neuropsychological Test Battery	5–8 years
Nonverbal Tests[a]	
Comprehensive Test of Nonverbal Intelligence, 2nd Ed. (C-TONI-II)	6:0–89:11
Leiter International Performance Scale Revised, 3rd ed. (Leiter-3)	3:0–75+
Naglieri Nonverbal Ability Test-Individual Administration, 3rd ed. (NNAT-3)	5–18 years
Test of Nonverbal Intelligence, 4th ed. (TONI-4)	6:0–89:11 years
Adaptive Behavior	
AAMR Adaptive Behavior Scale-School, 2nd ed. (ABS-S2)	3–21 years
Adaptive Behavior Assessment System, 3rd ed. (ABAS-3)	0–89 years
Scales of Independent Behavior-Revised (SIB-R)	infancy–80+ years
Vineland Adaptive Behavior Scales, 3rd ed.	0–90 years
Vineland Social-Emotional Early Childhood Scales (SEEC)	0–5:11
Diagnostic Instruments	
Anxiety Disorders Interview Schedule for Children (ADIS-C)	5–17
Child and Adolescent Psychiatric Assessment	8–17

(CAPA)	
Children's Interview for Psychiatric Syndromes (ChIPS)	6–18
MINI International Neuropsychiatric Interview for Children and Adolescents (MINI-KID)	6–17
Diagnostic Interview Schedule for Children (DISC-5)	6–17
Schedule for Affective Disorders and Schizophrenia for School-aged Children (K-SADS) and computerized version of KSADS (KSADS-COMP)	6–18
Projective Tests	
Children's Apperception Test	3–10
Draw-a-Person Technique	5–17
Kinetic Drawing System for Family and School	5–20
Rorschach Inkblot Test	5–adult
Roberts Apperception Technique for Children: (Roberts-2)	6–18
Rotter Incomplete Sentence Blank	Child–adult
Thematic Apperception Test	6–adult

[a] The KABC-2, DAS-II, and SB5 also yield nonverbal composite scores.

Modified with permission from Tsatsanis K, Hart L, Powell KK. Psychological and neuropsychological assessment of children. In: Martin A, Bloch MH, Volkmar FR, eds. Lewis's Child and Adolescent Psychiatry: *A Comprehensive Textbook.* 5th ed. Wolters Kluwer; 2018:321–335.

Objective personality tests are usually more structured than are projective tests, in that the stimuli have limited ambiguity, and only a select number of responses are permitted. In most objective measures, individuals are asked whether various statements are true or false for them.

Validity and Reliability

Although the validity and reliability of individual tests, as measures of specific mental functions, are established with group data, the reliability and validity of findings for the individual child are also a concern for the examining psychologist. Test batteries provide some advantages in determining the reliability and validity of individual test results. An integrated battery contains some overlap in the testing of mental functions, permitting comparative assessment of the consistency of the child's performance across measures. In addition, if there is a theoretical or empirical basis for knowing that some mental abilities are associated with each other, then consistent findings across measures of those abilities strengthen the confidence in the findings for the individual child. Examinations that focus on a few mental functions, by administering a limited number of tests, do not permit detection of transient performance factors that may cause spurious scores. In addition, no test is a pure measure of the target variable; therefore, performance on a single test may be impeded by impairment of a mental function necessary for performing the task but not the function that the test purports to measure. If previous psychometric evaluations have been performed, reliability of findings for a particular child can be estimated from the consistency of findings across examinations. While reliability is limited by various performance factors on the day of testing, data can still provide very useful insight as a snapshot of the child's current functioning (e.g., current depressive episode). Implications of testing biases are taken into account in the interpretation of results, discussed below.

Finally, the assessment of children with motor, language, hearing, or visual impairments presents a special challenge. Every psychological measure requires a modality of perception, mental processing, and modality of expression. To assess children with impairments in any of these functions, tests are selected with forms of input and expression that avoid the obviously impaired functions. Children with pervasive disorders of mental processing require assessment methods appropriate for their level of functioning. In such cases, it is frequently more helpful to characterize the impairments in terms of criterion-referenced measures, which list abilities mastered, or in terms of the child’s standing among children of the same diagnostic group.

Interpretation of Psychometric Findings

The interpretation of psychometric findings is predicated on standardized administration of the tests. In addition, the proper interpretation of psychometric findings generally requires knowledge of parametric and nonparametric statistics, mastery of the literature concerning test performance and test construction, familiarity with the construction and psychometric properties of the specific tests employed, and knowledge of the literature regarding those instruments.

The results of psychological examination are often best integrated in a concluding discussion of the findings as they pertain to the referral question. The results of a neuropsychological examination are organized around a discussion of various functions with a concluding integration. The interpretation of test results includes consideration of the immediate context in which the tests were administered (e.g., performance factors, such as fatigue, anxiety, rapport, level of cooperation and motivation of the child and examiner bias). There are generally three levels of analysis for the test scores: (1) pathognomonic symptoms, (2) levels of performance, and (3) syndromes or patterns. There is no direct interpretation for single scores. During syndrome analysis, scores are interpreted within the context of the results of other measures, which is the most powerful form of analysis in terms of the ability to extrapolate beyond the immediate tests data. This capacity to extrapolate is based on known characteristics of children evidencing the syndrome. Finally, when testing children, one must bring a developmental perspective to findings, so that future difficulties can be anticipated with the changes that occur as the child grows older.

Psychometric findings are communicated directly to the referring provider and to the family along with the data provided in a comprehensive report. These data are more easily understood if the psychological examiner first helps those receiving the findings understand some basic principles of psychometrics. First, the psychological examiner often explains (often by drawing a graph for visual representation) that most people cluster around some average score for standardized measures of mental abilities. This implies that fewer individuals score in the high or low ranges compared to the average range. The distribution approximates a binomial distribution in the form of an inverted U, known as the *normal curve.* Raw scores are frequently the number of correct responses during a test and are not usually reported. Percentile scores indicate the percentage of persons obtaining raw scores equal to or less than the raw score obtained by the individual. In the normal distribution, small changes in raw scores close to the average (where many people are grouped) result in relatively large shifts in the percentile rank, whereas large shifts in raw scores at the high and low ends of the distribution may change the person's percentile rank little.

To compensate for the variations in the rate of change of percentile scores, and to make performance levels comparable across tests, raw scores are converted to standard, or deviation scores that indicate the extent to which the individual deviates from the mean or average. By convention, the *average standard score for most psychological tests is 100*, and the *standard deviation is set at 15* IQ points or standard score points. By the use of standard scores, performance levels for measures of specific mental abilities can be compared with IQ or with other test results. Standard scores also give the best indication of significant differences among scores, because the intervals between scores of the same magnitude are equal anywhere along the distribution of scores. Statistical significance occurs when the probability is low that a difference between scores could have occurred by chance, as the result of inherent error variance in the test. By convention, a level of .05 probability is set as the standard for statistical significance. Although two scores may significantly differ, that does not mean that the difference is meaningful or has clinical significance. Many statistically significant differences occur frequently in the normal population. For example, a difference of 15 points between the Verbal and Performance IQ scores of the WISC-IV is statistically significant; however, a difference of this magnitude or greater occurs in approximately one-fourth of the normal subjects used to standardize the test. Of course, a difference of this magnitude could have clinical significance in a particular case, if the adverse effect of the difference was exacerbated by other factors.

Some tests for children allow calculating standard scores from age norms or grade norms, for example, the Woodcock–Johnson Psychoeducational Battery and the Kaufman Tests of Educational Achievement. The difference between these two methods of calculation illustrates the importance of understanding tests scores in relation to the normative reference group. A standard score based on age norms compares the performance of a child to that of other children the same age. A standard score based on grade norms compares the child's performance with that of other children in the same grade. If the child has been retained in grade to compensate for learning problems, the standard score based on grade norms is artificially inflated, masking the extent of the child's impairment. However, an achievement score based on grade norms indicates how well the child has mastered the curriculum at the grade level. In general, grade scores (grade and months) and age scores (years and months), as opposed to standard scores, should be interpreted cautiously, because their psychometric properties are poor, and the implications of the scores vary across levels. Clinical decisions should not be based upon these types of scores.

There has traditionally been a concern about reporting IQ scores, because people do not understand that the scores are not absolute and immutable. Reporting the standard error of measurement or confidence intervals helps others realize that scores have inherent error and vary to some extent over successive administrations of the test, even when the test is valid and reliable by present standards. Confidence intervals are the range of scores believed to contain the true score at a specified level of probability. The WISC-IV and WJPB-III scoring programs, for example, will calculate confidence intervals for standard scores, at 90% and 95% probability. Higher levels of confidence necessitate larger ranges of scores.

Report of the Psychometric Findings

Ordinarily, the child's parents are informed of the results of a psychological or neuropsychological evaluation during a feedback session, typically without the child. Children may receive a separate session to communicate relevant information from the testing, such as relevant clinical information and treatment recommendations that apply to the child. During this feedback session, the psychological examiner presents and discusses the results of testing and the clinical implications. Because tests scores are easily misinterpreted, reports of psychological test findings should never be given to the family without opportunities to answer questions.

A written psychological report is typically provided for the family during the feedback session. The report provides a detailed description of the tests administered, scored data, and the impressions and conclusions based on the data. The report is designed to be shared with whomever the child's parents choose, usually the referring provider, other members of the child's treatment team, and the school. It is important to note that confidentiality guidelines state that it is the *parents' choice* whether or not to share the results of their child's evaluation. For example, parents may not wish to share the report with the school because they do not want it included in the child's academic record. Thus, it is best practice to provide the written report directly only to the parents so that they have a chance to read the report thoroughly and share it with those whom they choose. Of course, clinical information is to be never released or shared without obtaining a written permission for the release of information. Furthermore, some examiners and parents may agree that it is best to provide a separate written report for the school containing test finding and relevant academic recommendations, while limiting the amount of other sensitive information about the family and the child.

PEDIATRIC AND OTHER ADJUNCTIVE EVALUATIONS

Pediatric Evaluation

Close collaboration with the child's pediatrician is usually an important component of any evaluation. The pediatrician is a valuable source of information about the child's developmental and medical history and can contribute a unique long-term perspective on the child and family. Especially when the pediatrician has had a longitudinal relationship with the family, they can also serve as an important source of support.

In addition to a general review of systems, the pediatrician should assess the child's current and past physical growth, including head circumference, height, weight, and pubertal status. Screening of hearing and vision, with more detailed testing as indicated, is important because deficits in these areas can manifest themselves in learning, language, and social delays or seeming inattention or oppositionality. History taking includes abnormal movements or absence spells suggesting seizures, abnormal postures, and tics. The physical examination notes difficulties in muscle tone and strength; asymmetrical, abnormal, or primitive reflexes; tremor; and gait or postural disturbances.

Especially in children with intellectual disability or autism spectrum disorder, a thorough history and physical examination can provide important clues to an underlying detectable medical cause. For children with developmental difficulties, a careful history of perinatal risk factors is taken; the pediatric examination includes careful evaluation for major or minor congenital anomalies, dysmorphic features, dermatologic abnormalities (tubers, fibromas, and areas of hyperpigmentation), or ophthalmologic findings (lens abnormalities and retinal pigmentation). Loss of previously acquired developmental milestones or the presence of congenital anomalies, dysmorphic features, microcephaly or macrocephaly and other growth problems, abnormal skin pigmentation or lesions, and symptoms suggesting seizure activity or other neurologic abnormality warrant more detailed genetic, metabolic, or neurologic evaluation.

Diagnostic Laboratory Tests

The clinical usefulness and cost-effectiveness of routine laboratory tests for children who present with psychiatric problems has not been substantially demonstrated. Most guidelines for performing these tests for children have historically been developed using data from studies of adults. Adult studies generally suggest that routine laboratory tests are not clinically useful in typical psychiatric settings, such as outpatient clinics and most inpatient units, although laboratory screening tests may be of some use in psychiatric settings in which patients are at high risk of medical illness, such as the emergency room, substance abuse treatment centers, AIDS clinics, and geriatric clinics, as well as for those who have new-onset psychosis, depression, or dementia or when evaluating children with developmental disturbances, such as intellectual disability or autistic spectrum disorder. Similarly, routine screening laboratory measures are more likely to yield clinically significant information when clinical symptoms of physical illness are present.

Evidence suggests that if anything, routine laboratory testing is less useful in pediatric compared to adult populations, where medical comorbidity that causes psychiatric manifestation is less common. The few studies of the use of routine laboratory tests in child psychiatry patient populations have yielded similar conclusions. One review of routine laboratory screenings (e.g., thyroid function tests, electroencephalogram [EEG], chest x-ray, chemistry panel, urinalysis, complete blood count, electrocardiogram [ECG]) in 100 consecutive adolescent inpatient admissions reported variable rates of abnormal values, depending on the specific test, but in only 1 of these 100 patients did the tests produce a change in diagnosis from functional to organic—and even then the diagnostic information proved to have little clinical relevance. Most laboratory abnormalities in this study were regarded as minor and did not indicate a need for clinical follow-up.

Similarly, routine use of more specialized diagnostic laboratory evaluations (EEG, computed tomography [CT], magnetic resonance imaging [MRI], or chromosomal analyses) also provide a relatively low yield of clinically useful information in most cases. In a study of 200 consecutive child psychiatric inpatients, these evaluations were performed only when clinically indicated; despite their judicious use, the tests provided clinically relevant information in only 7 patients

(3.5% of the total patient sample) or in 7 of 136 tests (5.1% of all tests performed). Chromosomal analyses proved to be the most informative of all these tests, yielding new medical diagnoses in 5 of 32 (15.6%) selected children for whom they were performed. A study of 111 putatively high-risk inpatients with new-onset adolescent psychoses produced similar conclusions. In this population, routine endocrine and neuroimaging screening evaluations failed to provide any information of diagnostic usefulness in any patient (although inconsequential laboratory abnormalities were present in 15.4% of the neuroendocrine screens and 11% of the neuroimaging screening tests). Structural neuroimaging assessments are typically of greater utility in children presenting with significant deficits in neurologic or cognitive function, atypical or abrupt presentation of psychiatric illness, or a history of head trauma. More specialized neuroimaging technologies, such as positron emission tomography (PET), single-photon emission computerized tomography (SPECT), and functional MRI (fMRI), currently have no routine clinical or diagnostic usefulness in child and adolescent psychiatric populations.

Two useful screening diagnostic tests in child psychiatric practice include (1) urine drug screening when indicated, and (2) testing for sexually transmitted diseases in high-risk patients. Substance use can cause a wide range of neuropsychiatric symptoms and mimic a large spectrum of psychiatric conditions. The high prevalence of substance abuse in adolescent populations has prompted recommendations that toxicology screens be obtained for (1) all adolescents who have psychiatric symptoms or who exhibit acute behavioral changes; (2) high-risk adolescents, such as delinquents and runaways; and (3) adolescents who have recurrent accidents or unexplained somatic symptoms. The possibility of substance use must always be considered as a cause of unexplained behavior in adolescents and it is likely that urine drug screening is often underutilized in clinical practice (especially emergency settings). Similarly, children and adolescents should be screened for risk factors associated with sexually transmitted diseases. Children and adolescents at risk due to either a history of sexual activity (or sexual abuse) or intravenous substance use should be evaluated for sexually transmitted diseases, including HIV infection and syphilis.

In contrast to routine screening, targeted laboratory testing in specific child psychiatric syndromes can be quite useful in (1) detecting the etiology of conditions or (2) uncovering treatable, high-risk medical comorbidities. Specific characteristics of a child's presentation can often trigger targeted diagnostic testing. For instance, testing thyroid functioning should be considered in the evaluation of a depressed adolescent, especially one presenting with prominent low energy, weight gain, menstrual irregularities, and/or brittle hair. Similarly, targeted diagnostic testing may be triggered when a child's psychiatric presentation places them at increased risk for specific medical conditions. For instance, children with intellectual disability or autism spectrum disorder may particularly benefit from targeted diagnostic testing. In general, the more severe the child's disability, the greater is the likelihood of an identifiable (albeit not necessarily treatable) cause. For example, one study found that a medical cause could be identified in 60% to 70% of children with severe intellectual disability versus only 35% to 55% of children with mild intellectual disability. Chromosomal abnormalities, especially trisomy 21 (Down syndrome) or fragile X syndrome, account for more than one-half of cases of intellectual disability. Children with autism spectrum disorder have relatively high rates of intellectual disability, seizure disorder (20% to 40%), and tuberous sclerosis (3% to 9%). Most experts would therefore advocate a Wood lamp examination to search for tubers, an EEG to exclude seizures, and high-resolution chromosome analysis to exclude known genetic syndromes in children who display features of autism spectrum disorder or intellectual disability. Identification of genetic causes of autism is now possible in more than 10% of affected children and, as current knowledge of specific genetic syndromes advances, high-resolution DNA sequencing is likely to increase the ability to discern specific subtypes of neurodevelopmental disorders.

Lead testing is also indicated in cases of intellectual disability because chronic lead ingestion due to pica can cause substantial retardation; conversely, many children with intellectual or pervasive developmental disabilities from other causes indulge in pica and may accumulate a substantial lead burden.

Finally, periodic laboratory testing (as well as tracking height and weight) is also important when starting certain psychiatric medications or monitoring for potential adverse during ongoing administration. For instance, height and weight must be tracked in youngsters on long-term stimulant medication and weight, hemoglobin A_{1C}, and fasting glucose and lipid profile in patients starting and continuing antipsychotic medications.

DIAGNOSTIC FORMULATION AND RECOMMENDATIONS

In the diagnostic formulation, the clinician attempts to integrate the data gathered through the assessment process into a coherent account of the child's difficulties, the factors that appear to have predisposed the child to develop the problem, the concomitants and consequences of the problem, and the factors that maintain the problem or that might ameliorate it. It is not always possible to provide a complete formulation at the conclusion of the initial assessment; under such conditions, the best that the clinician may be able to provide is a differential diagnosis that can point toward the appropriate treatment options and the subsequent steps needed to clarify or establish a diagnosis.

One product of the assessment may be the assignment of a diagnosis of one or more categorical psychiatric disorders using the diagnostic schema of DSM-5-TR or ICD-11. Although these nosologic systems have done much to standardize diagnostic practices and to improve the quality of research, one must be aware of their clinical limitations as applied to children. Many children experience sufficient symptoms, distress, or impairment to be regarded as psychiatrically disturbed and to warrant therapeutic intervention without meeting the full criteria of a categorical psychiatric disorder. Furthermore, as currently conceptualized, the DSM-5 classification is descriptive and atheoretical; it specifies neither presumed etiology nor treatment for the various diagnostic categories. If the assessment process is to provide a picture of the child that suffices to guide intervention, the resulting diagnostic formulation must go beyond simply assigning a categorical psychiatric diagnosis (if one is warranted). As noted in the introduction, comorbidity is often the rule rather than the exception in childhood, and many children have complex patterns of developmental and behavioral difficulties that are not adequately captured by a list of multiple categorical diagnoses. Children who share a given categorical diagnosis may differ in crucial respects that influence current severity, natural history, and treatment response. Examples of potential risk (or exacerbating) factors and protective (or ameliorative factors) include intelligence, compensatory skills, family and community resources and supports, and vulnerabilities, such as comorbid pathologic personality traits, neurologic impairments, coexisting general medical conditions, or family pathology.

The clinician's diagnostic formulation should thus supplement the assignment of any formal categorical diagnoses by attempting to identify, as far as possible, the potential causes, predisposing factors, and current determinants of the child's difficulties. On the basis of this information and the clinician's expertise regarding the various interventions available for the diverse forms of childhood psychopathology and developmental difficulties, the clinician formulates appropriate recommendations for the treatment of the child's problems.

Communicating Findings and Recommendations

Communicating the findings and recommendations that result from the assessment to the parents and child is an essential part of the evaluation process and may require one or more sessions. Depending on the problem and the child's age and level of comprehension, presenting the findings usually involves meeting with the child and parents, separately or together.

Several principles must be observed to maximize the likelihood that the parents and child hear, understand, and experience the clinician's findings and recommendations as helpful. First, the clinician must communicate a sense of the child as a whole person, with strengths and abilities, as well as problems and vulnerabilities. This perspective conveys a sense of the clinician's appreciation and empathic understanding of the child, reduces defensiveness, and helps to mitigate the fear that there is only bad news.

The findings and recommendations are most useful to the family and likely to be implemented if the interpretive session is a dialogue rather than a lecture. The clinician must use language comprehensible to the parents and child, must avoid jargon, and must keep technical terms to a minimum. When technical terms are necessary, they should be explained clearly, so the parents and child understand them; terms that are merely descriptive to the clinician may hold frightening or negative connotations for the child or family. The clinician should allow ample opportunity for the parents and child to discuss the recommendations and to discuss any questions. This provides a chance to judge whether the clinician's formulation made sense to the family, to address any differences of opinion, and to explore the feasibility and acceptability of the recommendations offered. Remaining areas of uncertainty or ambiguity about the assessment or recommendations should be clearly noted and discussed.

If the assessment is a consultation requested by an agency, a school, or another clinician, the findings and recommendations should be communicated to the referring party in appropriate terms after being discussed with the parents and child and obtaining their consent. If further evaluation or treatment is indicated but is best done by someone else, the clinician should offer to assist in finding an appropriate referral.

35.2 Psychiatric Assessment of Preschool Children

HELEN LINK EGGER, M.D., AND CAROLY SUE PATAKI, M.D.

The infant/preschool mental health field has made real strides in recent years in demonstrating that clinically significant psychiatric symptoms and disorders are already present and highly impairing in early childhood. Recent epidemiologic studies of children ages 2 to 5 years old have shown that the overall rate of psychiatric disorders in preschoolers is remarkably similar to the overall rates reported for older children and adults. For example, the preschool rate of "serious emotional disturbance," defined as psychiatric disorder(s) that are associated with significant impairment, was 12.1%, 9.1%, and 7.1% in three different community preschool studies, compared with a median rate across community studies of 13.2% in older children and adolescents and 15.6% in adults. The growing recognition of the mental health needs of preschool children reveals a large gap in mental health services. Few clinicians have training in the assessment and treatment of young children. This section provides an overview of the components of comprehensive, empirically based psychiatric assessments of preschool children and their families.

DEVELOPMENTALLY APPROPRIATE CRITERIA FOR PSYCHIATRIC SYMPTOMS AND DISORDERS IN PRESCHOOL CHILDREN

Historically, young children's emotional and behavioral problems have been approached dimensionally, with cut-points set to characterize subsets of children at the extreme of the distribution of (1) normative behaviors and emotions and/or (2) temperament traits. In these models, extremes of problems or temperament traits have typically been regarded as precursors of, or risk factors for, later psychopathology rather than as psychiatric disorders similar to those identified at later stages of life. Although symptom checklists or temperament measures often provide clinically useful information about the young child, they do not have the symptom coverage (particularly for rare but highly concerning symptoms such as suicidality or stereotypies) nor details about the characteristics of symptoms (e.g., frequency, onset, duration) to enable the clinician to make a diagnosis. There have been two approaches to the diagnostic classifications of early childhood psychopathology (1) the *Diagnostic and Statistical Manual of Mental Disorders/International Statistical Classification of Diseases and Related Health Problems* (DSM/ICD) diagnostic classification, either unmodified or modified to be developmentally appropriate for young children, and (2) the Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood (DC:0-3 [1994], DC:0-3R [2005], and DC:0-5 [2016]), an alternative system for classifying mental health disorders in infants, toddlers, and preschoolers. These categorical approaches seek to identify clinically significant syndromes, characterized by severity, pervasiveness, persistence, and impairment, that are early-onset “disorders” rather than simply risk factors for later disorders.

Despite its lack of developmental specificity, the DSM has been a useful starting point for examining how psychopathology presents in early childhood, at least in children 2 years old or older. For example, the diagnostic criteria of the fifth edition of the DSM (DSM-5) and its text revision (DSM-5-TR) work quite well as a means of advancing the current understanding of the presentation and course of autism spectrum disorders despite its lack of developmentally specific criteria. The dual approach of testing the applicability of current diagnostic criteria for identifying autism spectrum disorders in young children while exploring the validity and clinical utility of developmentally specific criteria and/or diagnostic algorithms for use with young children provides an exemplary road map for examining the validity of specific behavioral and emotional disorders in young children. Similar approaches are being taken in studies of early-onset attention-deficit/hyperactivity disorder (ADHD), anxiety disorders, depression, post-traumatic stress disorder, and disruptive behavior disorders in young children. The challenges of applying the DSM criteria to young children are greater than in later childhood because of the limitations of children’s language expression and cognitive development, the rapidity of developmental change during the first 5 years of life, and the greater interdependence of very young children on their caregivers.

There have been two approaches to the development of a mental health classification system for young children: a top-down and a bottom-up approach.

The top-down approach begins with the nosology used for adults and older children and then proposes developmentally appropriate modifications of these criteria. In 2003, the Research Diagnostic Criteria-Preschool Age (RDC-PA) was published with the goal of facilitating further research on the diagnostic validity of psychiatric disorders in preschoolers by defining clearly specified, developmentally appropriate criteria for preschool psychopathology. The RDC-PA explicitly sought to modify the DSM criteria to make them developmentally appropriate rather than to propose a new classification system. The RDC-PA facilitated research on the nosology of disorders in young children.

The alternative approach seeks to start with the young child and use clinical and scientific knowledge about infants, toddlers, and preschoolers to characterize mental health disorders in a separate classification. The first edition of the DC:0-3, published in 1994, reflects the “bottom up” approach. The 2005 revision of the DC:0-3 (DC:0-3R, 2005) and the most recent version, DC:0-5, combined the two approaches, as well as explicitly addressing the crosswalk between the separate early childhood classification and the DSM/ICD. The DC:0-3R and DC:0-5 sought to incorporate research and clinical expertise to operationalize the characteristics of diagnostic criteria and, where possible, explicate differences in presentations in infants, toddlers, and preschoolers. The diagnostic classification includes alternative criteria for DSM-5-TR diagnoses, new diagnostic categories (e.g., regulation disorders of sensory processing), and a multiaxial system.

The 2016 DC:0-5 represents the most significant revision of the early childhood classification. Key changes to this version include: One, the name of the classification was changed to DC:0-5 to reflect a common understanding that “early childhood” spans from infancy through the preschool period and to align the title with the fact that early childhood practitioners have been using the nosology through the preschool period despite the name. Second, to distinguish between transient changes in a young child’s emotions or behaviors or typical individual differences, the DC:0-5 requires child distress or the child’s and/or the family’s functional impairment for every disorder in order to avoid pathologizing nonclinical presentations. Third, despite the fact that the DSM no longer uses a multiaxial system, the DC:0-5 retained the multiaxial system, primarily to emphasize the importance of context for understanding psychopathology in young children. The DC:0-5 axes were substantially revised. All disorders, including relationship disorders, are recorded on Axis I, while the characteristics of the caregiver–child relationship are recorded on Axis II. Axis V was revised to reflect the child's developmental competencies. Lastly, all disorders relevant to the young child are included in the classification (previously, users were referred to the DSM when DMS disorders such as autism spectrum disorder were appropriate for use with young children). The manual does include a "crosswalk" from each DC:0-5 diagnosis to a parallel DSM and ICD diagnostic codes to enable the early childhood nosology to be integrated into mainstream nosologies and to facilitate billing for services.

What System Should a Clinician Use?

At this point, it is quite clear that the DC:0-5 is the current diagnostic nosology for diagnosing psychopathology in infants, toddlers, and preschoolers. In addition to the developmentally sensitive criteria, the DC:0-5 manual includes information about the presentation, prevalence, course, comorbidities, risk factors, and differential diagnoses for each disorder. As noted above, the DC:0-5 manual includes a "crosswalk" from DSM-5 codes to DSM/ICD codes because these codes are often needed to obtain insurance reimbursement for services.

COMPREHENSIVE, EVIDENCE-BASED PSYCHIATRIC ASSESSMENTS OF PRESCHOOL CHILDREN

There are five key components of a comprehensive psychiatric assessment of a preschool child: (1) multiple sessions, (2) multiple informants, (3) a multidisciplinary approach, (4) multiple modes of assessment, and (5) a multiaxial diagnostic formulation. These components arise from the multidisciplinary, developmental, relationship-based, family-centered, and prevention-focused orientations that characterize the infant/preschool mental health field's approach to understanding psychopathology in early childhood.

Multiple Sessions

Despite the real reimbursement constraints that clinicians face in conducting multisession evaluations, these constraints cannot dictate the length of an evaluation. It is simply not possible to conduct an adequate psychiatric assessment of a young child in one session. Although it could be argued that this caveat is true for all of pediatric psychiatry, the rapid developmental, cognitive, emotional, and behavioral changes that characterize the preschool period, as well as the young child's physical and emotional dependency on their primary caregivers, make it imperative that information be gathered about the child across sessions and across time. For example, a tired 3-year-old child seen after a long day at preschool may look quite different when seen in the morning after they have had a good night's sleep. The best practice is for the clinician to see the parent(s) without the child for one of the sessions so as to obtain a detailed history of the child's symptoms and the family history and current family structure and functioning. It is essential to obtain information about current and past parental psychiatric and substance abuse problems and treatments, domestic violence in the home, and marital (or partner) difficulties, but it is not appropriate to discuss these issues in front of the child. Nor is it appropriate for the child to hear negative comments about himself or herself (e.g., "He is a bad kid") or to be privy to a parent's worst fears ("I am afraid that he will end up like my brother who killed himself"). These comments and fears are very important pieces of information about how the parent sees this child. Any parent of a preschooler also knows that it is quite difficult for young children to refrain from interrupting adult conversation long enough for the clinician to obtain the breadth and level of detail needed to understand the child's problems. However, even if the child is seemingly absorbed in play in the corner of the office, they will hear the adult conversation. An evaluation should include phone sessions with the child's teacher or child care provider (written consent to contact the teacher or child care provider should be obtained at the first session). A visit to the child's daycare or preschool to observe the child's functioning with other adults and peers in an out-of-home setting may also be indicated.

Multiple Informants

The clinician must gather information from multiple informants. First and foremost, the child is an important informant. This is as true of a 2-year-old with limited expressive language as of a 5-year-old about to enter kindergarten. Information can be obtained by speaking with and/or playing with the child (using structured or unstructured approaches) and observing the child interacting with parents, with another clinician, and with teachers or childcare providers, or peers. It is not possible to assess or diagnose a young child based on parent reports alone. Moreover, the clinician should make every effort to spend time alone with the child without the parents present (severe separation anxiety is an example of a disorder that might make this very difficult).

Of course, an evaluation cannot be conducted without information from the child's primary caregivers. These may be the child's biologic parents and/or adults who act as parents of the child, such as step-parents, grandmothers, or foster parents. An evaluation should include a three-generation genogram identifying the important parental figures and family members (including psychiatric and substance abuse history for each member). Ideally, if there are two parents in the home, both of them will attend the evaluation sessions and fill out all measures and information separately. Often each parent provides a somewhat different description of the child's symptoms. This does not undermine the validity of these reports but rather reflects the fact that the child shows different aspects of themselves within different relationships. This information is diagnostically important and may be useful in guiding treatment planning. The parents will also provide information about themselves (e.g., current psychiatric symptoms and treatment, parental and marital stress). Information must also be obtained from the child's nonparental caregivers, such as teachers or child care providers, nannies, and babysitters who spend a significant amount of time with the child. As described in more detail in the next section, other clinicians, such as the child's pediatrician, are also critical informants.

Multidisciplinary Assessment

A child psychiatrist conducting a preschool psychiatric assessment usually collaborates closely with other clinicians and care providers, including psychologists, primary care and developmental pediatricians, neurologists, occupational therapists, speech and language therapists, early interventionists, case managers, adult psychiatrists and psychotherapists who treat the disorders from which the parents may be suffering, and marital therapists. The child psychiatrist has an opportunity (if not an obligation) to assume a leadership role among all of these care providers. At the evaluation stage, the child psychiatrist should integrate the assessments and recommendations made by other providers into their assessment and then facilitate treatment planning and coordination of communication among these providers. The child psychiatrist should never provide treatment for a young child, particularly treatment with psychotropic medication, without having conducted a comprehensive assessment themselves.

Multiple Modes of Assessment

Because it is not possible to conduct a standard psychiatric interview with a young child about their emotions and behaviors, preschool mental health assessments must draw on information gathered using different approaches, including adult reports, observational assessments, structured or unstructured play/interactions with the child, and standardized psychopathology, cognitive, motor, language, and other developmental assessments. A physical exam (often conducted by the child's pediatrician) is essential. Laboratory measures, including genetic testing, may be indicated.

When possible, empirically tested measures with demonstrated reliability and validity should be used to assess child and family domains. Types of measures include symptom checklists, such as the Strength and Difficulties Questionnaire, which is valid for children 2 or older, the Child Behavior Checklist 1½-5, the Infant Toddler Social Emotional Assessment for children 12 to 36 months old, DSM-referenced rating scales such as the Early Childhood Inventory-4 (ages 3 to 6 years), and checklist measures of specific symptom clusters such as the ADHD Rating Scale or the Spence Preschool Anxiety Scales. Teacher/Caregiver measures such as the Caregiver-Teacher Report Form, as well as those assessing social skills and peer relationships, such as the Social Skills Rating System, are also useful. Similar types of rating scales are available to assess adult domains, such as psychopathology (e.g., Mood and Feelings Questionnaire), parental stress (e.g., Parenting Stress Index), or domestic violence (Conflict Tactic Scales).

In the future, structured diagnostic parent interviews for assessing preschool psychopathology will be the best way to obtain comprehensive psychiatric, developmental, and environmental information about the child and the family, but these measures are not yet user-friendly enough for use in clinical settings. The exception is the Autism Diagnostic Interview

(ADI). The Preschool Age Psychiatric Assessment (PAPA) is currently the only comprehensive parent psychiatric interview for assessing psychiatric symptoms and disorders in children ages 2 to 5 years with demonstrated test-retest reliability and validity. There is also a version of the PAPA for assessing nonpervasive developmental disorder (PPD) symptoms in children with autism and other PPDs (PAPA-PDD). The ePAPA, a web-based version of the PAPA (and PAPA-PDD) to be administered on a tablet personal computer, which is part of the eMeasures system, is used in research studies but has not yet been developed for use in clinical settings.

Direct “interviews” with the young child about their feelings and experiences are also an essential component of a comprehensive assessment. In most clinical practices, unstructured play is used to learn about the child’s emotions. Structured child interviews, such as the MacArthur Story-Stem Battery (MSSB), have shown some promise for children 4 years old and older. Children tell us what they are feeling and experiencing through their play and their behavior. Unlike older children and adults, young children do not yet have the skills to share verbally how they are feeling or to regulate their emotions. Dysregulated early childhood behaviors such as temper tantrums are as common to be a sign of an emotional disorder as a “behavioral” disorder.

Observational assessments, particularly of parent–child interactions, play an important role in preschool assessments. Inspired by the success of the Autism Diagnostic Observational Schedule—a structured assessment for autism in which the examiner “presses” for PDD symptoms with specific tasks with the child—researchers have developed a similar diagnostic observational measure for assessing disruptive behavior disorders in preschoolers (Disruptive Behavior-Diagnostic Observational Schedule [DB-DOS]). The same group has developed a similarly structured observational measure of emotional disorders for use with preschool children.

There are numerous standardized, developmentally specific measures for assessing the preschooler’s status in cognitive, language, motor, and preacademic domains. Reviews of specific measures in this and the other areas mentioned in this section can be found in the textbooks listed in the reference section.

Multiaxial Assessment

A comprehensive psychiatric assessment in the preschool age group must be truly multiaxial, with each axis reflecting the developmental and relationship-based framework of infant and early childhood mental health. Since DSM-5-TR no longer uses a multiaxial system, coding on the DC:0-5 system provides an opportunity for clinicians to be comprehensive in assessing children’s emotions and behaviors within the context of their relationship with their primary caregivers, their medical history, their history of trauma and adversity, and their developmental competencies across the domains of emotional, social-relational, language-social communication, cognitive, and movement/physical development. In addition to the DC:0-5 manual and Zero to Three’s DC:0-5 training, there are excellent infant/early childhood mental health books, including the *Handbook of Infant Mental Health*, the *Handbook of Preschool Mental Health*, and the *Handbook of Infant, Toddler, and Preschool Mental Health Assessment*.

The child’s symptoms across all axes must be understood within the child’s current level of functioning across multiple developmental domains (e.g., cognitive functioning, expressive and receptive language, gross and fine motor skills, prekindergarten knowledge, and social-emotional skills). These developmental assessments are important for (1) understanding the child’s psychiatric symptoms within their developmental capacities (not simply the child’s chronologic age), (2) identifying developmental lags or deficits that can be effectively addressed (e.g., expressive language problems), and (3) ruling out (or ruling in) the presence of a developmental disorder such as a speech delay. Because children 3 years old and younger (and in some states 5 years old and younger) are eligible for early intervention services for developmental delays, it is critical that child psychiatrists identify these delays and provide appropriate treatment referrals.

Assessment of the context of the child’s symptoms, as well as the child’s environment within and outside of the family, is also vital. The pervasiveness of the child’s symptoms, not only across settings but also across relationships, will provide important information about the nature of the symptoms. For example, if a child has explosive tantrums that occur when the child is at home and at school and occur with the parent and with the child’s daycare provider, the child may well be showing a symptom of an emotional or behavioral disorder. The child who has similar tantrums only when separating from their mother may be experiencing a symptom of an anxiety disorder. The child who only has tantrums when being dropped off for a custody visitation with a divorced parent may be expressing distress that arises from the difficulty of moving back and forth between two parental homes. The child who only has tantrums with their mother but shows good emotional and behavioral regulation with all other adults may be showing signs of a relationship disturbance with the mother. The infrequent tantrums that occur only when a child is exhausted (e.g., after a long car trip traveling home from a visit with Grandma) may very well be developmentally normal. These examples highlight the importance of obtaining detailed examples of the child's behaviors with a focus on the characteristics of the symptoms. Relevant questions include the following: What does the child do or say? How often does it happen? How long does it last? When did it start? What triggers the symptom? When, where, and with whom does the symptom occur? What helps? This descriptive information is not the same as asking the parent, "Why does your child do that?" Often, one does not know "why," but detailed descriptions of specific symptoms provide the information needed to rule in or rule out specific disorders. An important difference between DSM and DC:0-5 is that the DC:0-5 provides a place (Axis II) to record information about the relational context of the child's symptoms. Part A of Axis II characterizes the caregiver's and the infant/young child's contribution to their relationship and their mutual adaptive functioning. Part B examines the caregiving environment and the caregiver and child's adaption to this environment.

Assessment of the child's environment and how stressors impact the child is also essential. In the DC:0-5 systems, psychosocial and environmental stressors and risk factors are listed on Axis IV. DC:0-5 includes a broad (but not inclusive) checklist of known stressors, along with a place to indicate the age of onset, duration, severity, and context of these stressors, which is meant to provide a guide to the assessment of this domain. Axis IV should reflect a careful history of the child's environment, including, to name a few, an understanding of (1) parental/family factors such as a family history of psychiatric and substance abuse disorders and treatment, including types and doses of psychotropic medications and types of psychosocial treatments (a history of postpartum depression should be obtained), family structure and functioning including a careful assessment for physical or emotional abuse or neglect and sexual abuse, parent–partner relationship functioning including an assessment of adult-adult domestic violence and emotional abuse, and sibling relationships; (2) pregnancy and birth factors, including premature birth, low–birth-weight, maternal smoking or use of other substances during pregnancy, neonatal complications, and maternal depression during or following the child's birth; (3) the child's school or day care experiences, including teacher–child ratios, frequency of changes in child care settings and providers, amount of time the child is away from parent(s), age when the child started out-of-home care, peer relationships, and relationships with nonparental child care providers; (4) community factors, including neighborhood safety and proximity of relatives; and (5) socioeconomic factors, including parental employment status, family's social economic status, and absence of health insurance. Major stressors (e.g., parental divorce, death of a parent, physical abuse, hospitalization, or natural disasters such as a house fire or hurricane) known to be potentially traumatic life events should be included. However, chronic stressors or those that may seem "minor" (e.g., change in daycare, moving to a new house) should also be included on Axis IV. There is clear evidence that the accumulation of multiple stressors with varying intensities has as profound an impact as single traumatic events in early childhood, just as they do in later childhood and adolescence. Both acute and cumulative stressors significantly raise the risk that the child will have one or more psychiatric disorders and be impaired.

CLINICAL FORMULATION AND TREATMENT PLANNING

Clinical formulation is an integrative skill that involves the pulling together of multiple observations and sources of information about an individual within a general diagnostic scheme so as to guide decision-making. It is worth emphasizing that a psychiatric nosology classifies disorders, not individuals. When a comprehensive psychiatric evaluation has been conducted with a preschool child and their family, and the DSM and/or DC:0-5 axes have been completed, a clinical formulation about the child and a treatment plan addressing each of the child's challenges areas should be developed. Clearly defined symptoms within the child must be identified, ideally using measures that are sensitive to change, so that the clinician will be able to assess the efficacy of the intervention and the outcome of treatment. Of course, the assessment may also identify targets for treatment beyond the child's mental health symptomatology. For example, a treatment plan might include a referral of the child for speech or occupational therapy or a referral of a parent for treatment of their depression.

The evidence is quite clear that approximately 10% to 15% of preschoolers have severe impairing psychiatric disorders that cause suffering and put them at risk of ongoing emotional and developmental problems. These children and their families deserve effective and safe treatment. The evidence base for psychiatric treatments for preschoolers is emerging. There is every reason to hope that there will be major advances in the current understanding of the etiology and course of early-onset mental health problems, as well as the development and dissemination of effective treatments and preventive interventions. However, children and their families cannot wait for the research to catch up with this need. Clinicians who treat preschoolers must (1) know the current state of evidence on the assessment and treatment of preschool psychopathology, (2) know how to decide on and determine the efficacy of treatments that may not have been studied in young children, and (3) be committed to keeping up with and incorporating new findings into their practice. Clinicians and parents should together weigh the risk of the disorder(s) with the risk of treatments so that parents can make fully informed decisions about how to best care for their child. Single-case experimental designs (e.g., *n*-of-one trial) that seek empirically to determine the efficacy of treatments for preschool patients are the best ways to manage these risks. This is particularly vital when the use of psychotropic medication is being considered. The guidelines for the psychopharmacologic treatment of preschoolers recommend this empirically driven (and cautious) approach to treatment. The infant/preschool mental health field has always had an early intervention and prevention orientation. The hope is that the identification and treatment of preschool children with clinically significant psychiatric symptoms and disorders will not only ease their suffering during early childhood but also will contribute to ameliorating or even preventing the onset of new disorders or progression of these disorders into later childhood and adulthood.

35.3 Neuropsychological and Psychoeducational Assessment of Children

EVANGELINA BARNARD, PSY.D., AND PATRICIA D. WALSHAW, PH.D.

This section describes the process, application, and interpretation of cognitive assessment of children. Within the umbrella term of cognitive assessment, it is useful to differentiate two common yet different methodologic approaches to child assessment: neuropsychological and psychoeducational assessment. Both neuropsychological and psychoeducational assessments are undertaken as ways of understanding the referral questions of children and adolescents and how the processing of information can affect a wide range of adaptive functions. Although testing procedures in these types of assessments might overlap, these approaches analyze behavior according to two different paradigms. The psychoeducational assessment focuses on assessing a child's intelligence and learning style to inform academic and school-based interventions. Neuropsychological assessment is undertaken in the context of growing knowledge about brain–behavior relationships, and it has the additional possibility of describing the child in terms of neural pathways. These approaches provide ways of conceptualizing how children integrate information (and their thinking, learning, and responding) at different levels. The psychoeducational assessment focuses on understanding the child's functioning at a more behavioral level (i.e., whether a child shows learning difficulties in certain areas) and in descriptive terms. Neuropsychological assessment introduces the additional possibility of understanding such behavior at neural levels and in neurobiologic terms. However, regardless of the theoretical differences among the psychologists undertaking these evaluations, in a practical way, it is the patient's referral question that shapes the assessment process and focuses the interpretation of results.

BASICS OF COGNITIVE ASSESSMENT

Cognitive assessment involves more than testing. Although measurements are useful, testing involves more than scores.

The Testing Process

In addition to testing, assessment procedures include examining past records (medical examinations, prior testing, report cards), interviewing the client and their family (in structured and unstructured formats), obtaining information from home and school (and, sometimes, on-site observations), and obtaining rating scales completed by the child's parents and teachers (regarding developmental, behavioral, emotional, and diagnostic concerns). The diagnostic aspect of the process involves an attempt to determine the psychiatric and educational categories for which the client meets the criteria. Testing is only an aspect of an attempt to establish a broad view of the way a child solves problems in the world, to understand their unique interaction with any diagnostic category, and to provide recommendations for interventions. Once quantitative data from any type of evaluation are gathered, they mean nothing without a qualitative interpretation, as well as a conceptualization and presentation that helps to make sense of the child client to their caretakers. Feedback about results and their relationship to the presenting problems can be provided as the evaluation unfolds. Often this discussion is among the first opportunities the parents have had to understand the patient's predicament in a detailed, sympathetic way and to begin a constructive process. It can be helpful for the family to comprehend the patient's difficulties as a natural outgrowth of problems with understanding and learning, so long as practical interventions and solutions are provided.

Measurements in Testing

Although many techniques might be used to help understand a child client and their referral question, the emphasis here is on standardized testing (based on regularized procedures as well as normative data). The aim of testing is to create a way of comparing one individual to a population of such individuals, as well as the strengths and weaknesses within one individual. The psychologist will select an instrument that is valid (it measures what is intended) and reliable (it measures it consistently).

There are different ways of describing a child's placement compared to others of the same demographic, the most common of which are standard scores and percentiles. This involves converting raw scores to standard scores that can be compared to other scores along what is thought of as a normal distribution with predictable statistical properties. It should be noted that there are different kinds of scores and values within the normal distribution and that they differ by mean and dispersion. (Fig. 35.3–1, which depicts Z, T, and intelligence quotient [IQ] scores, as well as rounded percentiles under the "bell" curve.) While standard scores (such as those with a mean of 100) can be informative, parents often respond well to the concept of a percentile. For example, a student who falls at the 68th percentile performs as well as or better than 68% of the children tested. In addition to percentiles and standard scores, many cognitive tests provide age equivalents or grade equivalents. These measures suggest how the child compares to others of their age or grade.

It should be noted that tests are constantly updated. This is often undertaken to correct perceived shortcomings, adjust for cohort changes, and to make instruments more relevant. Because of this, instruments are referred to in "generic form" in this text without any notation that would identify the edition. However, in actual practice, it is important to know that the clinician has used the most up-to-date version of the test unless there is a good reason not to. For example, some clinicians with specialized practices continue to use old editions (or subtests) of instruments because they find that particular instruments or tasks best meet the needs of their particular population or best answer a type of diagnostic question.

(American Psychological Association guidelines require essentially that the tests used to make interpretations or recommendations are not outdated or obsolete for the “current purpose.”) Clinicians must select from among the available tests the one that seems to best meet the needs of any particular client. Table 35.3–1 notes the editions of tests that are current as the present text goes to press.

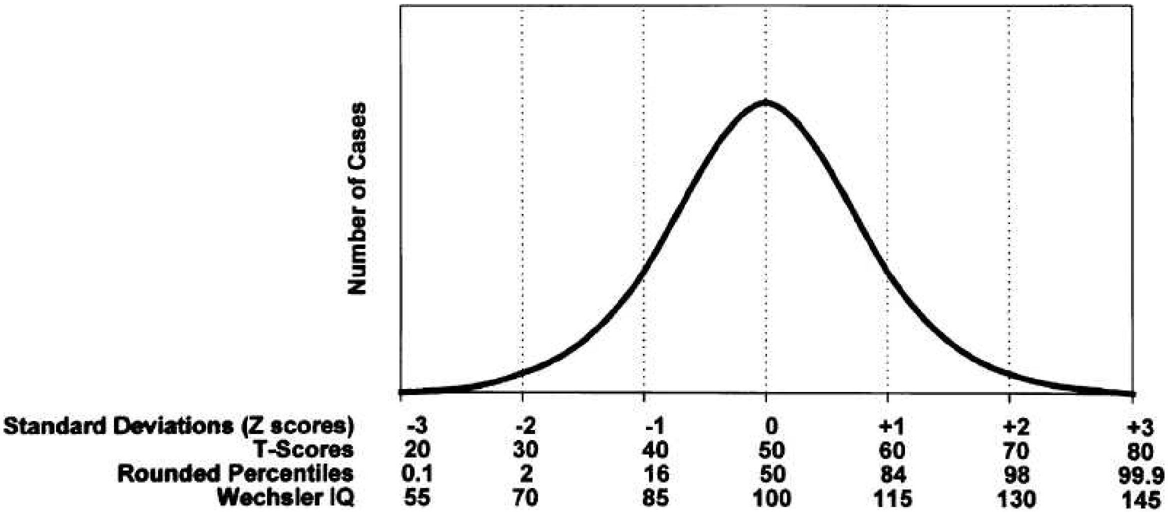

FIGURE 35.3–1. Normal curve and standardized scores.

Cultural and Linguistic Considerations

Cultural and linguistic factors are important considerations in both conducting psychoeducational and neuropsychological evaluations and interpreting findings. Research exploring how an individual’s culture influences their approach to, and performance on, various measures has highlighted discrepancies and raised awareness about the cultural “fairness” of cognitive measures.

Culture provides a framework for ways of thinking, feeling, and behaving (Ardila, 2013). An individual’s cultural background can influence how they approach the assessment, which in turn can impact their perceived performance. For example, while the speed of performance may be valued and understood in Western cultures, other cultures place a much higher value on answering carefully and correctly. Timed measures emphasizing speed over accuracy may therefore produce greatly different results across cultures. Many object naming tests utilize items common to western cultures but rare or unknown in other cultures. In addition to influencing the approach to test measures, culture may also influence how an individual relates to the examiner, their comfort level with the assessment, and their willingness to share details of their medical history and symptoms.

Historically, the majority of assessment measures have been normed on White, non-Hispanic monolingual English-speaking individuals (Casas et al., 2008). While some efforts to improve the diversity of normative data have been undertaken, particularly in adult populations, most assessment norms for children remain relatively homogenous. The impact of this disparity in norms can be seen in test performance across individuals of different ethnic and linguistic backgrounds. For example, one study demonstrated that African American preschool children were significantly more likely to be classified in the “impaired” range on the Expressive Vocabulary Test (EVT) and Peabody Picture Vocabulary Test (PPVT) language tests as opposed to their non-Hispanic White classmates. Another study demonstrated that African American, Hispanic, and Native American children typically perform lower on IQ and achievement tests as compared to their non-Hispanic White counterparts. Indeed, a lawsuit in California in 1979 resulted in a ban on utilizing IQ tests to identify whether African American children should be placed in special education classrooms. Similar disparities in test performance are seen in bilingual and multilingual children as compared to monolingual English-speaking children. These are a few examples; however, they underscore the importance of considering the cultural context of the child being assessed.

If an individual is bilingual or multilingual, ensuring that the assessment is conducted in their primary as well as secondary language(s) is key to gaining a comprehensive understanding of their cognitive abilities. In an ideal scenario, this assessment would be conducted by a trained psychologist who is fluent in the same languages, utilizing measures that have been standardized as well as normed on the population in question. Unfortunately, in many cases, this ideal situation is not feasible due to either lack of appropriate standardized measures, available trained practitioners, lack of norms, or all of the above. If a trained practitioner is not available, the use of a medical interpreter combined with measures normed within this population may be used, although a caveat should be made on the interpretation of the data. Often, appropriate norms are regrettably not available, and assessment with an interpreter utilizing standard norms is conducted with the caveat that the results are more qualitative and may not fully capture the individual’s abilities.

When reviewing an assessment report, it is important to note whether the examiner has identified the child's cultural and ethnic background and the languages in which the child is fluent. Furthermore, as a report consumer, it will be key to identify whether the examiner attempted to utilize the most appropriate norms, acknowledged the impact of culture and ethnicity on the assessment proceedings, and ensured the child was assessed in all proficient languages.

Beyond Scores and Tests

It should be noted that the testing process involves more than scores. Although scores are important, how the patient goes about solving cognitive problems also is carefully observed. The examiner is interested not only in test performance but also in behavioral observations—the client's reaction, types of errors they are making, and behavior during testing. It is important for the psychologist to note how the client arrives at right as well as wrong answers and to explore the client's cognitive strategies on tasks. In general, it is important to note whether the client responds in a deliberate or impulsive way. It also makes a difference to the examiner whether the child says, “This is easy,” as they fail, or laments, “Oh, this is hard,” as they succeed. Both give the examiner a very different sense of how the client will experience school and life.

Although the focus here is on the assessment of broad cognitive functioning and targeted domains, depending on referral issues, the evaluation might also address behavioral, social, and emotional issues using a variety of techniques. It is well established that emotional, behavioral, and social issues can affect cognition and learning and vice versa. The psychologist will use reports from parents and teachers, observations, and test data to examine how these issues are playing a role in the overall picture of the child. These are integrated with other cognitive assessment data to help clarify diagnosis and aid in treatment planning. Specific information about processing problems (how the child perceives their experience and monitors their behavior, and therefore responds to their situation) can help adults to know better how to interact with the child, as well as plan appropriate educational and interpersonal interventions.

Table 35.3–1.
Cognitive Domains and Tests

Domain	Age Range	Description
Intellectual Tests		
Omnibus Intellectual and Ability Tests		
Wechsler Preschool and Primary Scale of Intelligence–Fourth Edition (WPPSI-IV)	2 years, 6 months–7 years, 7 months	These tests consist of several subtests that can be combined in different ways to understand basic intellectual functioning. Many, if not most, cognitive tests (including intellectual, achievement, and domain targeted) are structured in the same way (mean is 100, standard deviation is 15), and so results can be compared across instruments. This is particularly important in identifying learning problems. The Wechsler tests and SB5 yield a full-scale IQ score, as well as overall scores across several indices (e.g., verbal, visual, fluid reasoning, working memory). The KABC scales and their subtests (which minimize verbal instructions and responses) include measures of sequential
Wechsler Intelligence Scale for Children–Fifth Edition (WISC-V)	6–16 years, 11 months	
Wechsler Adult Intelligence Scale–Fourth Edition (WAIS-IV)	16–90 years, 11 months	
Stanford–Binet Intelligence Scales–Fifth Edition (SB5)	2–85+ years	
Kaufman Assessment Battery for Children–Second Edition (KABC-II)	3–18 years	
Woodcock–Johnson–Fourth Edition Tests of Cognitive Abilities (WJ-IV COG)	2–80+ years	
Differential Ability Scales–Second Edition (DAS-II)	2 years, 6 months–17 years, 11 months	
A Developmental Neuropsychological Assessment–Second Edition (NEPSY-II)	3–16 years, 11 months	

		and simultaneous processing, fluid reasoning and crystallized ability, and long-term retrieval. The WJ-COG scores provide information about intellectual ability, as well as a variety of cognitive and clinical areas. The WJ-COG is co-normed with the WJ-ACH, and the new test of oral language (WJ-OL). The DAS provides a measure of general conceptual ability and a profile of cognitive strengths and weaknesses. While it is not a classic intellectual test and does not provide an IQ measure, the NEPSY provides scores across a variety of cognitive domains (executive functioning/attention, language, sensorimotor, visuospatial, memory/learning, and social perception).
Nonverbal and Language-Free Ability Tests		
Leiter International Performance Scale–	3–75+ years	These tests are often given to assess abilities

Third Edition (Leiter-3)	6–89 years, 11 months	in the absence of language. This can be used for both individuals who have language difficulties and those who do not speak English and where no tests/interpreter are available in that language/culture. Although the nonverbal tests are often seen as language or culture free, strictly speaking, this is not always true because of representational content or language demands. However, some nonverbal tests (such as the TONI-4) depend more on abstract pattern recognition and can make fewer demands on language systems. The WNV provides batteries for younger (4–7:11) and older clients (8–21:11), and claims to be a general ability measure using nonverbal tests. Tests like Raven's Progressive Matrices (which actually come in several forms) are
Test of Nonverbal Intelligence–Fourth Edition (TONI-4)	6–89 years, 11 months	
Comprehensive Test of Nonverbal Intelligence, Second Edition (CTONI-2)	4–21 years, 11 months 5–17+ years	
Wechsler Nonverbal Scale of Ability (WNV)		
Raven's Progressive Matrices		

		based on pattern recognition and thought of as “culturally reduced,” if not unbiased or unloaded. Nonverbal tests can be useful in assessing individuals whose experience falls outside the “cultural norm.”
Quick Intellectual Tests		
Kaufman Brief Intelligence Test–Second Edition (KBIT-2) Wechsler Abbreviated Scale of Intelligence-Second Edition (WASI-II)	4–90 years 6–90 years, 11 months	The KBIT and WASI include verbal and nonverbal scores, but do not include as much information as more comprehensive intellectual tests. However, they provide an estimate of intellectual level in a fraction of the time.
General Achievement Tests		
Wechsler Individual Achievement Test–Fourth Edition (WIAT-4) Woodcock–Johnson Tests of Achievement-Fourth Edition (WJ-IV ACH) Kaufman Test of Educational Achievement–Third Edition (KTEA-3) Wide Range Achievement Test–Fifth Edition (WRAT5) and WRAT-Expanded (WRAT-E)	4–50 years, 11 months 2–80+ years 4–25 years, 11 months 5–94 years 4–24 years	Tests in this domain measure academic performance (knowledge and fluency of academic skills—reading, writing, math). The WRAT5 includes subtests on sentence comprehension, word reading, spelling, and math computation. An expanded version (WRAT-E) provides achievement and

		intellectual information (nonverbal reasoning). The KTEA assesses reading (decoding and comprehension), mathematics, spelling, and written expression. The WIAT and WJ-ACH also systematically address the basic areas that have been identified as relevant for learning disability. The WIAT-4 includes a Dyslexia Index Composite.
Reading Tests		
Gray-Oral Reading Tests–Fifth Edition (GORT-5)	6–23 years, 11 months	The WRMT (which includes a measure of listening comprehension) and GORT (which includes a measure of fluency) involve systematic approaches to assessing different aspects of reading skills. Because of the importance of phonologic awareness in the development of reading skills, tests of phonologic processing (such as the CTOPP) are often included in assessments in which reading problems are identified.
Woodcock Reading Mastery Tests–Third Edition (WRMT-III)	4 years 6 months–79 years, 11 months	
Comprehensive Test of Phonologic Processing–Second Edition (CTOPP-2)	4–24 years, 11 months	

Language Tests		Tests in this domain assess language abilities, either globally or targeting a specific aspect (i.e., expressive, receptive, pragmatic). The PPVT assesses receptive language while the EVT assesses expressive language. The CELF-5 provides a comprehensive assessment of language skills.
PPVT, Fifth Edition (PPVT -5)	2 years, 6–90+ months	
EVT, Third Edition (EVT-3)	2 years, 6–90+ months	
Clinical Evaluation of Language Fundamentals, Fifth Edition (CELF-5)	5–21 years, 11 months	
Attention and Executive Functioning		Tests in this domain assess attention and/or executive functioning abilities. As a test of executive functions, nine stand-alone subtests in the DKEFS assess cognitive flexibility, response inhibition, problem solving, and concept formation. The CPT-3 is a computerized measure of sustained attention, impulsivity, and vigilance. The WCST assesses problem solving, cognitive flexibility, set shifting, and impulsivity.
Delis–Kaplan Executive Function System (D-KEFS)	8–89 years, 11 months	
Conners' Continuous Performance Test, Third Edition (CPT-3)	8+	
Wisconsin Card Sorting Test (WCST)	6 years, 5 months–89 years	
Visuospatial and Visual–Motor Tests		
Bender Visual–Motor	4–85+ years	These tests assess

Gestalt Test–Second Edition (Bender-Gestalt II) Beery Developmental Test of Visual–Motor Integration–Sixth Edition, Revised (VMI-6) Test of Visual Perceptual Skills–Third Edition (TVPS-3) Benton Judgement of Line Orientation (JOLO)	2–99 years, 11 months 4–18 years, 11 months 7–74 years	abilities in visual processing, including visual/perceptual reasoning (*what* an object is or how it is constructed), visual/spatial reasoning (*where* an object is in space), and visual/motor integration. Both the Bender and VMI involve copying geometric figures. Because the Bender allows the student to organize the items on the page and the VMI asks the student to copy each figure in its own space, the two can be used together to assess organizational issues, as well as visual–motor integration. Both the current versions of the Bender and VMI provide ways of assessing perceptual separate from motor skills. The TVPS and Benton are motor free and involve making judgments about visual information—for example, on the TVPS, a client might be asked

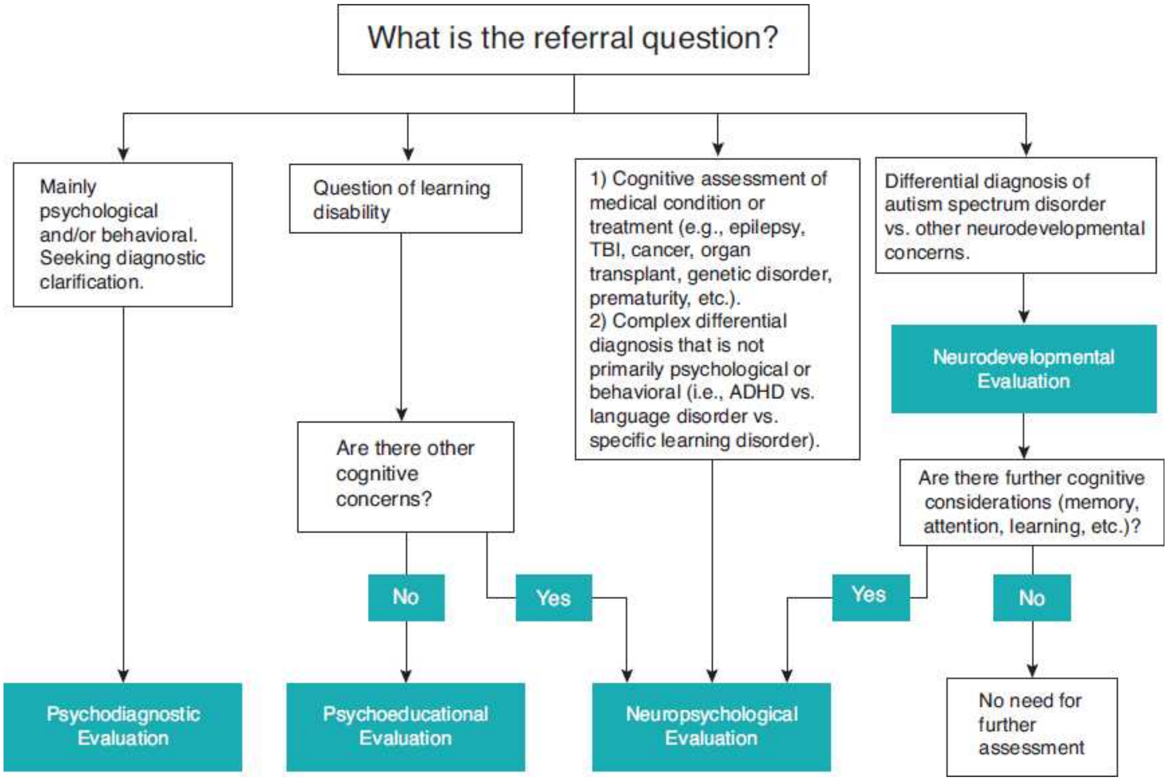
		to identify an item from a fragmented presentation while on the Benton a client is asked to identify which lines are in the same spatial orientation.
Auditory Processing Tests		
Test of Auditory Processing Skills–Third Edition (TAPS-3)	4–18 years, 11 months	Tests in this domain assess the ability to process auditory information. The TAPS involves making judgments about auditory information. The TARPS measures the “quality” and “quantity” of the client’s auditory thinking and reasoning.
Test of Auditory Reasoning and Processing Skills (TARPS)	5–14 years	
Memory Tests		
Wide Range Assessment of Memory and Learning–Second Edition (WRAML3)	5–90 years	Memory scales attempt systematically to assess memory skills within different spheres. The WRAML3 core battery consists of verbal, visual, and attention/concentration subtests. The CMS allows for the assessment of attention and working memory, verbal and visual memory, short-delay and long-delay memory, recall and
Children’s Memory Scale (CMS)	5–16 years	
Child and Adolescent Memory Profile (ChAMP)	5–21 years	

		recognition, and learning characteristics. The ChAMP consists of two verbal memory subtests and two visual memory subtests.
Social Cognition and Language		
Test of Problem Solving–3: Elementary (TOPS-3:E)	6–12 years	These tests assess social cognition and reasoning through language as well as indirectly assessing use and understanding of the social pragmatics of language. Elementary and adolescent clients are asked to answer questions about pictures or scenarios to reveal social reasoning.
Test of Problem Solving–2: Adolescent (TOPS-2:A)	12–17 years	
Test of Pragmatic Language–Second Edition (TOPL-2)	6–18 years, 11 months	A test of language used to achieve goals, with information about six areas (setting, audience, topic, purpose, cues, and abstraction).

Note: This table is meant to be a representative list of commonly used tests but is not a comprehensive list of every test available in each domain. Publishers are constantly updating their tests, and these editions will be superseded by newer and better tests. Even now, there may be variations of some instruments that are supplemented, expanded, or newly normed.

PSYCHOEDUCATIONAL AND NEUROPSYCHOLOGICAL ASSESSMENT

Psychoeducational and neuropsychological assessment can be looked at from different perspectives as clinicians attempt to understand referral questions and individual children. Testing instruments can be used in a more “comprehensive” (i.e., measuring a variety of cognitive domains) or more "focused” (i.e., measuring one or two cognitive domains) manner to answer the referral question. Cognitive domains that are explored in testing include intellectual functioning, achievement (academic) functioning, memory, attention, executive functioning, language, visuospatial, and sensory/motor functioning. A common question asked by psychiatrists is what type of evaluation is needed for their specific patient. This is based on the referral question (see Fig. 35.3–2) in order to optimize recommendations for treatment. Often patients are referred for a “comprehensive neuropsychological evaluation” as a kitchen-sink catchall when a focused evaluation may be more helpful in answering the referral question without unnecessary tests, time, and strain on the child and family.



What is the referral question?
Mainly psychological and/or behavioral. Seeking diagnostic clarification.
Question of learning disability
1) Cognitive assessment of medical condition or treatment (e.g., epilepsy, TBI, cancer, organ transplant, genetic disorder, prematurity, etc.).
2) Complex differential diagnosis that is not primarily psychological or behavioral (i.e., ADHD vs. language disorder vs. specific learning disorder).
Differential diagnosis of autism spectrum disorder vs. other neurodevelopmental concerns.
Neurodevelopmental Evaluation
Are there other cognitive concerns?
Are there further cognitive considerations (memory, attention, learning, etc.)?
No
Yes
Yes
No
Psychodiagnostic Evaluation
Psychoeducational Evaluation
Neuropsychological Evaluation
No need for further assessment

FIGURE 35.3–2. Psychological assessment referral algorithm.

Psychoeducational Assessment

Psychoeducational assessment, as described here, is particularly suited for the evaluation of learning issues as they affect school functioning. Psychoeducational assessment involves the combination of intellectual, achievement, and domain-targeted tests to determine the cause of learning problems, as well as, at least in the past, to establish eligibility for services with public schools. These types of evaluations are best when the question is more focused on a specific learning issue (e.g., suspicion of reading disorder, accommodations for learning disorders on standardized tests). Psychoeducational evaluations include measures of academic function (i.e., reading, writing, math, etc.) and fluency and also include basic intellectual function measures for references. Oftentimes assessment of attention deficit hyperactivity disorder (ADHD) is included in this type of evaluation with select measures of attention, and executive function added.

Over the years, the basic definition of learning disability as “unexpected underachievement” has remained, but with new understanding and meaning. In this context, it should be emphasized that there are two different systems for identifying learning problems: currently, Specific Learning Disabilities in school settings and Specific Learning Disorders in clinical settings. For many years, learning disabilities and disorders were essentially interchangeable because of their focus on a severe or substantial (significant) discrepancy (typically one standard deviation [SD] or more) between ability and achievement. However, educational and medical definitions of learning deficits under Individuals with Disabilities Education Act (IDEA) and DSM, respectively, have changed.

In schools, the current IDEA 2004 language forbids states to present a severe discrepancy model to local educational agencies as the only option and indicates they must allow for other possibilities. Underachievement may be identified in several areas (focusing on reading, mathematics, and written expression). Basically, this can be based on failure to respond to research-based intervention as other students have or the identification of a pattern of weaknesses in the context of strengths that indicates a specific learning disability.

In clinics, the new definition provided by the DSM-5 focuses on an absolute academic deficit and stipulates two basic requirements. The first requirement is that the learning difficulties have persisted for at least 6 months “despite the provision of interventions that target those difficulties.” The second requirement is that academic skills (in reading, written expression, or mathematics) should be “substantially and quantifiably below those expected for the individual’s chronological age” and cause significant interference with related activities, “as confirmed by individually administered standard achievement measures and comprehensive clinical assessment.” The new definition also requires two additional factors: that the learning difficulties begin in the school-age years, although they might not become manifest until later, and that the learning difficulties are not better explained by other issues, such as intellectual disability, other disorders, or inadequate instruction. The exact deficit level associated with the learning disorder might be left to the clinician’s judgment, but the threshold is thought to be between 1 and 2.5 SD below the population mean (100), depending on the circumstances of the case. A 1 SD standard would fall at or below 85 (16th percentile); this might be sufficient for diagnosis “with converging evidence.” A 1.5 SD standard would fall at or below 78 (7th percentile); this level is thought to provide “more diagnostic certainty.” Specific learning disorder is an umbrella term, but impairments can be specified in the three academic areas and can involve efficiency as well as accuracy. The severity of the disorder can be specified from mild to severe. The clinical standard for learning disorder might be seen as stricter (if not clearer) than the school standard for learning disability.

For learning problems, educational research has suggested just how complicated the identification of learning difficulties is, while recognizing the need to define them in order to provide services to children, particularly in school. Descriptions and definitions of learning deficits have recognized disparities in different aspects of functioning and tried to parse out factors intrinsic to the child and specific to learning from aspects of their environment and experiences. Procedural definitions of learning disorders under the DSM in the medical community and of learning disabilities under IDEA in the public schools have tried to grapple with this complexity. As a practical matter, both have generally focused on the concept of “unexpected underachievement.”

When it comes to learning disability, what is at stake is the opportunity for a patient to obtain services through school at no cost to the family. Otherwise, it falls to the family to obtain private educational therapy in the community. In schools, students might obtain targeted classroom instruction in areas of weakness, or some intervention through a student study team, or accommodations or modifications in class through informal

504 procedures. However, students are apt to receive more extensive and expensive services under IDEA, through more formal Individualized Education Program (IEP) procedures that identify and make recommendations around disabilities, including specific learning disability.

Neuropsychological Assessment

Neuropsychology is dedicated to the study of brain–behavior relations and has matured into a clinical discipline for the diagnosis and characterization of brain function and dysfunction. This type of assessment is provided by a clinical neuropsychologist with advanced training and expertise in neuropsychology.

Assessment of Functioning. Neuropsychological assessment was originally developed for the assessment of adult patients and was not generally applied to child assessment until later. When it was used, it was typically to assess children's functioning subsequent to acquired injuries or diseases affecting the brain. This functional assessment was important because the effect of trauma on the brain is highly variable across individuals, even when the precise location and size of the lesion are known. In these situations, neuropsychological tests could provide specific functional information that took the child's age and developmental status into account. This continues to be a prominent point of referral for pediatric neuropsychology because it discusses not just the existence of the brain disruption but its *meaning* in terms of the child's ability to function.

Developments in Test Instruments. Advances in pediatric neuropsychology include the introduction of tests specifically designed for use with children. These instruments assess similar behaviors as do their adult counterparts but use paradigms that are more engaging to children and better measure developmental transitions throughout childhood. These instruments are used in clinical assessments but are now also part of many research protocols examining childhood diseases and genetic conditions. Given its precision in measuring behavior, neuropsychological assessment is now involved, not just in the assessment of function after an injury but also in the initial diagnostic processes. Another example of this specificity is the now-routine use of neuropsychological testing in genetic research of developmental disorders of childhood, given the precision that it adds to questions of endophenotype expression.

Applications of Neuropsychological Assessment. The functional and diagnostic assessment of children and adolescents often begins (and ends) with psychoeducational evaluations. There are situations, however, in which the use of educational, intellectual, or psychological testing alone is not able to clarify the diagnosis and determine the most appropriate treatment plan. In those cases, the psychiatrist should consider additional neuropsychological testing. To help treating psychiatrists to know more about when to refer a patient for neuropsychological testing, the following list offers specific information about when this approach to testing might be helpful.

1. *Assessing brain function*: Neuropsychological tests are designed with the expressed intent of assessing brain function. Thus, if patients have a history of traumatic brain injury, neurologic condition (e.g., epilepsy, brain tumor, genetic disorder), or history of medical treatment with known CNS effects (e.g., chemotherapy), neuropsychological assessment would be the testing of choice. In these cases, identification of impacted neuropsychological circuits might contribute to diagnostic clarity and treatment planning (e.g., whether hippocampal vs. frontal circuits are contributing to memory impairment may aid in how to approach learning with a child).
2. *Complex diagnostic picture with clear cognitive issues*: Children presenting with complex diagnostic issues may benefit from neuropsychological evaluation if the psychodiagnostic evaluation does not elucidate a clear picture. For example, a child who presents with symptoms of ADHD and oppositional defiant disorder but who also has a history of language difficulties with speech therapy and poor performance in school may warrant a referral for neuropsychological testing to examine if attentional and oppositional issues are stand-alone or related to ongoing language and/or learning disorder.
3. *Breaking down cognitive functions to better assist with intervention*: Neuropsychological tests are valuable when a systematic assessment of a functional hierarchy might allow for a complex skill to be broken down into its component parts. For example, if a child works slowly on a reading fluency task, is the cause their reading problems or slow processing speed? Many neuropsychological tests employ a functional

hierarchy of demands that allow several basic aspects of a complex skill to be measured independently to reduce confounding variables and more confidently examine the specific behavior initially intended.

In addition, the neuropsychological battery contains many tests that appear to be very simple but are included because of the narrow range of abilities that are required for them to be done well. Examples of these are the examination of sensory skills, such as auditory processing in the right versus left ear, lateralized tests of motor development, such as grip strength or pegboard placing, and the administration of timed, simple tests across several skills to highlight selected low scores that fit into known patterns (such as the language-based weaknesses suggested by compromised rapid color naming alongside weak math automaticity).

4. *Very high or low intellectual level*: Another application of neuropsychological testing occurs in instances where the child is at the higher or lower end of the intellectual range where cognitive testing does not demonstrate a clear score profile. Bright children with learning disorders have many unaffected domains of strength that can be used to compensate on “multiple construct” tests to support the more discrete impairment. Although this will usually result in relatively lower-than-expected scores, in very gifted students, the bottom of the range of such scores may be average to high average, making interpretation difficult. It is important to note, however, that the ability to apply a clever strategy to a test does not mean that the student can likewise use intellect to manage their symptoms in the larger contexts of life (which is the reason the child presented for assessment in the first place). Rather, the child’s clever approach to testing means that there is a greater risk that all scores will cluster together at an above-average point and not demonstrate discrepancies that suggest learning problems. In these cases, students are often not diagnosed at all or until much later, after life’s demands have caused considerable disruption to their academic, social, and/or emotional success.

   Conversely, when a child’s intellectual functioning is very compromised, tests that do not include the functional hierarchies discussed earlier make it more likely that all scores will be low. This is a concern, given the importance of identifying relative cognitive strengths in these children, because these islands of ability can be quite amenable to intervention and so will demonstrate more improvement with treatment than the other, very impaired skills. When these children are young, they should receive intervention for both their areas of profound weakness and their relative strengths, but in adulthood, it will likely be the isolated strengths (which, with specific early intervention, will develop on a higher trajectory than those that are more impaired) that provide the foundations for future participation in aspects of adult life.

5. *Retest to check for treatment effects*: A last benefit of neuropsychological tests that may be important to a psychiatrist is that many of these instruments have been constructed so as to control for "practice effects" (an artificial increase of a score resulting because a test was given twice with too little time between the administrations). When practice effects are controlled, tests can be readministered at short intervals, providing an effective way of assessing treatments such as medication that should show rapid improvement in cognitive abilities. Although this approach needs to be undertaken cautiously (and results interpreted in light of slight improvements seen in nonclinical populations, as are known to occur with some medications), significant changes measured with retesting can add confidence to clinical observations obtained informally or with questionnaires.

   One way of managing practice effects is to have two alternate forms of the same test, which allows them to be readministered after only short intervals. Many subtests from the Delis–Kaplan Executive Function System (D-KEFS) provide these alternate forms, making them a good choice when disorders characterized by executive functioning deficits are part of the referral question. A second way of managing practice effects is with tests that are intentionally boring, such as those measuring sustained attention (e.g., the Connors Continuous Performance Test [CCPT]). When, after a short interval, children with normal attention retake the CCPT, they typically perform *worse* than they did the first time (contrary to what practice effects would suggest). The decrease in scores is attributed to the boring nature of this long, computerized test; the first time the child takes it, there is some excitement about its novelty, but by the second time, the child knows what they are in for from the start, which affects the child's motivation. If a child does significantly better on the second administration, the change is attributed to something other than practice; if done in the course of a medication trial for ADHD, the assumption is that the medicine is helping performance more than the practice is hurting it.

There are several ways that retesting can be used to aid a psychiatrist in quantifying medication effects. For example, when a child who is already on medication for ADHD presents for testing, a 45-minute battery that measures behaviors that are sensitive to the medicine can be administered one morning without medication and a second morning with it. Alternatively, if at the close of testing ADHD is a diagnostic impression and the treating physician thinks a medication trial is appropriate, the child can return for brief reassessment with sensitive tests once the medicine is thought to be at therapeutic levels. Information obtained from retesting can provide data about the benefit of the medication and the appropriateness of the dosing, as well as increasing parents' and patients' confidence about the intervention.

COGNITIVE DOMAINS OF ASSESSMENT

Although psychologists use diverse tests, there is a selection of domains that are measured during the assessment. Table 35.3–1 offers a sampling of tests that psychologists often utilize in neuropsychological or psychoeducational assessments. It should be noted, however, that all of these domains overlap to some degree. The role of the psychologist is to examine all of the data (cognitive, emotional, behavioral, and history) together and look for patterns while isolating areas of dysfunction in order to formulate a conclusion about diagnosis and provide treatment recommendations. A full range of cognitive domains, instruments, and their uses are described in this section.

Intelligence

Intellectual testing is often part of a variety of assessment batteries, including psychoeducational and neuropsychological evaluation, along with more general developmental and clinical evaluations. It is usually undertaken to determine the patient's general intellectual level of functioning. The IQ is valued because of its stability over time in the general population, as well as for the protective aspect of intelligence in a range of potentially disabling situations. It should be noted that, although intellectual level can be measured, it is hard actually to define intelligence.

Definition. Different theorists have had their own take on intelligence. Although, theoretically, Sattler saw intelligence as “multifaceted and hierarchically organized,” practically, there is no agreement about what intelligence is, and this is reflected in the different ways in which it is measured. However, a commonsense definition of intelligence would include the ability to learn from and adapt to the environment as well as the ability to think abstractly and to recognize patterns in diverse situations (on tests and in life). Although intelligence tests yield one IQ score (or several IQ or index scores), they are, in fact, devices for “sampling” many tasks in a variety of verbal and nonverbal areas.

Stability. Although there is some debate, IQ scores tend to be relatively stable starting as young as 5 to 7 years of age. In general, the older the child is when tested and the smaller the interval between test administrations, the greater is the correlation between two IQ scores. Although using an IQ score can be useful as a way of assessing the client’s basic trajectory through life, the prudent practitioner must be aware that there are a number of factors that can affect intellectual functioning and, thus, IQ scores. These factors can include psychiatric illness, lack of motivation, and inattention. In some cases, treatments and interventions implemented to improve cognition and development can improve functioning and, thus, IQ scores.

Protection. Despite conceptual and practical complications, high intelligence is associated with better prognosis in a wide range of psychiatric conditions; lower rates for behavior, conduct, and emotional problems in children; and lower rates of referral for psychiatric problems in adults. In the case of any kind of brain damage (neuronal death), intellectual level accounts for a great deal of variance in predicting overall cognitive and functional outcome, with lower IQs associated with poorer outcomes and higher IQs associated with better outcomes in general.

Assessment. Although IQ is what is obtained with an IQ test, there are a variety of intellectual tests, as well as other ways of calculating intellectual level. There are a number of instruments from which to choose, and the psychologist must make their selection based on the specific characteristics of each test (e.g., normative sample and construction of the instrument) as they relate to the characteristics of the client (e.g., age and referral question). Once the test has been administered, the clinician must make interpretations based on the analysis of overall and subtest scores and their pattern in the context of the diagnostic process. Intellectual tests can be supplemented by a variety of instruments to further characterize any patient's presentation, in order to contribute to their understanding and diagnosis, and to help identify appropriate interventions.

Sometimes, there are misinterpretations of scores at the bottom of the intellectual range. Distinctions must be made between level designations and diagnostic categories. The DSM-5 utilizes the term intellectual disability to describe those individuals who score within the lower end of the intellectual range. The term intellectual disability involves impairments in mental abilities that impact adaptive functioning in three domains (conceptual, social, practical). Severity of the disability is determined by adaptive level, not intellectual score, because it is those impairments that determine the level of supports needed. However, it is important that measurement of intellectual level still be part of any individual's assessment, along with developmental course and adaptive deficits. Under DSM-5, intellectual disability is associated with intellectual levels two SD or more below the population mean, or an IQ score of about 70 or below. In making determinations about low intellectual level, the psychologist must look at the pattern of strengths and weaknesses not only within the instrument, but also within the overall case presentation. For example, some IQ scores can be brought down by specific language disorders or perceptual–motor difficulties.

COMPREHENSIVE INTELLECTUAL TESTS. The two best-known intellectual tests are probably the Wechsler Intelligence Scales and the Stanford–Binet Intelligence Scales (SB). The current editions of both are divided into separate subtests, and the data are analyzed in separate spheres. Each test has an overall mean of 100 (50th percentile) and a SD of 15. Subtests have a mean of 10 and a SD of 3. In the case of the Wechsler tests, three separate instruments (Wechsler Preschool and Primary Scale of Intelligence [WPPSI], Wechsler Intelligence Scale for Children [WISC], and Wechsler Adult Intelligence Scale [WAIS]) are designed for three different age groups over the lifespan. For the SB, one instrument covers a lifetime. All instruments include full-scale IQ scores, as well as (broadly speaking) verbal and nonverbal composite scores. The SB provides an extended score range (at the top and bottom of the scale) that may make it more useful for individuals within the “gifted” and “impaired” ranges. Both the SB and the Wechsler tests have been the “standard” individual intellectual tests for the school-age population. They allow for the assessment of overall functioning and verbal and nonverbal reasoning. These instruments have taken care to relate to achievement tests to facilitate the recognition of learning disabilities according to a “traditional discrepancy model” in which estimated ability is compared to academic achievement. Intellectual testing is commonly a part of psychological evaluation as it provides a way of understanding a patient’s overall level of functioning in school and in life.

OTHER INTELLECTUAL TESTS. Sometimes, specific characteristics of clients, such as age, suggest the use of specific instruments.

1. *Infant and child tests*. Although very young clients can be “tested,” these administrations are often as useful for their observations as their scores. Because of the emphasis on sensorimotor functioning and development of language skills of very young clients, the instruments (such as the Bayley Scales of Infant and Toddler Development) are not as useful for predicting later IQ scores as they are for identifying individuals who are or are not, at risk. The instruments do not become predictive in a more specific way until children are of school age.
2. *Nonverbal and language-free tests.* Although some tests seem especially suited for individuals who have difficulty in hearing or have language issues (such as the Leiter International Performance Scale), the nonverbal tests can have broader applications. Their emphasis is on cognitive problem solving based on visual information. In fact, the Wechsler Nonverbal Scale of Ability claims to be a test of general ability using nonverbal tasks, not a measure of “nonverbal intelligence.” Although these nonverbal tests are useful, it is important to remember that they may not provide the whole picture, and the significance of these tests for the client’s ability and functioning must be carefully assessed.
3. *Quick tests.* The commonly used tests in research and clinical practice are the Kaufman Brief Intelligence Test (KBIT) and the Wechsler Abbreviated Scale of Intelligence (WASI). Both the KBIT and the WASI include verbal and nonverbal tasks to assess crystallized and fluid thinking. The WASI and KBIT2 have been able to provide evidence of good correlations with established Wechsler tests. The available data

suggest that the quick tests, in fact, yield very representative overall IQ scores. Although a clinician might not get all of the processing information included in a full intellectual test, these correlation coefficients suggest that the quick tests can provide a very good estimate of the client's general level of functioning.

General Comment. In discussing intellectual testing, it is important to note what IQ tests are and what they are not. Although IQ scores are commonly used as estimates of ability, they are not measures of "native" or "raw" intelligence. Every client brings a long learning history, including opportunities, to the testing situation. Although some instruments (such as those that emphasize nonverbal functioning) may seem less biased or loaded, it must be acknowledged that probably no intellectual test is either culture free or fair. Nonetheless, because of the way in which tests have been constructed and normed, caution has to be exercised in making conclusions in any case with a diverse cultural/linguistic background or unique medical situation. Although IQ scores are useful as estimates of ability, they are, in fact, measures of functioning. There are a variety of transient factors that can be associated with alterations in IQ scores, including problems with involvement, attention, and disorganization. As a result, the clinician has to be prepared for changes in intellectual level based on changes in medical status. For example, in some cases, clinicians have observed increases in IQ scores subsequent to medical treatment for ADHD, partly due to increased efficiency on the instrument itself and partly due to increased learning over time in the environment and in school. Further, clinicians need to be aware of what IQ scores do and do not measure. They do not measure social intelligence. Nor do they reflect the creativity that artists of different kinds bring to their art and that entertains and informs people daily.

Considerations. Here are a number of factors professionals should keep in mind when they deal with intellectual test results.

1. The intellectual instruments have developed classification systems according to intellectual level. The Wechsler system (based on scores with a mean of 100 and an SD of 15) utilizes the following classifications for standard scores: exceptionally low (≤69), below average (70 to 79), low average (80 to 89), average (90 to 109), high average (110 to 119), above average (120 to 129), and exceptionally

high (≥130). The Stanford–Binet test uses the same classification system for low average to high average scores (80 to 119). However, the classification system has a wider range including scores from 40 to 160, from moderately impaired or delayed to very gifted or highly advanced.

2. The more variability seen on intellectual testing, the less do composite or summary scores have utility. For example, on the WISC or SB, when the verbal and nonverbal scores (or other contributing indices or composites) differ significantly, the full-scale IQ is not informative. Similarly, when subtest scores differ significantly within a sphere, the emphasis should be on specific processing issues rather than overall functioning.
3. Sometimes a practitioner will ask what a patient’s IQ is. It is clear from the multiplicity of the tests and scores available that there is no one IQ. Although IQ is what the client gets on an IQ test, it is prudent to be well aware of which test was administered and which IQ is being quoted. The practitioner should be aware of disparities on different tests or in different areas; this pattern is often important in making decisions for a client.
4. In the context of a psychoeducational assessment, when scores differ significantly on intellectual testing, the full-scale IQ may not be the best estimate of “ability,” and the clinician will make attempts to choose among the possible summary scores on a range of instruments to identify the one that best represents the student’s learning potential.

Further Assessment. The following is a list of patterns that suggest the need for further evaluation.

1. *There are significant discrepancies between verbal and nonverbal scores*. When verbal scores are significantly lower than nonverbal scores, the possibility of a language disorder should be considered. In the case of low verbal scores, a speech and language assessment, including measures of receptive and expressive language, as well as pragmatics (the factors affecting successful communication), might be indicated. It is particularly important to identify language-based learning disorders because of their potential effect on school (and relating) and because there are some very specific treatments that might be helpful. When nonverbal scores are significantly lower than verbal scores, further assessment regarding a variety of possibilities must be considered. More than the verbal tasks, the performance

tasks (which might be timed) are vulnerable to ongoing and transient factors mediated by attention. In the case of particularly large discrepancies, the possibility of nonverbal learning disorder should also be considered. This is a pattern of cognitive assets and deficits that can be associated with peer, as well as academic, problems. The identification of a nonverbal learning disorder can be very helpful because it can lead to a wide variety of interventions, including those around social skills.

2. *The full or composite score is above the 98th or below the 2nd percentile (130 or 70)*. At the intellectual extremes, the examiner may consider whether further assessment regarding educational or adaptive needs might be in order. When a client has a very high intellectual level (e.g., moderately to profoundly gifted), the professional might refer the family to a psychologist specializing in very bright children. In the case of individuals with very low intellectual levels, further assessment can be obtained through the school system or the local public agency serving developmentally delayed clients. Professionals and parents may access the websites http://www.aaidd.org, http://www.thearc.org, and http://www.eparent.com for information about services and products associated with intellectual and developmental disabilities.
3. *The intellectual score shifts downward in a significant way*. Because it is anticipated that intellectual scores will remain relatively stable over time, the mental health professional is advised to look for an explanation, either psychological or medical, for dramatic score changes. This is a time when the psychologist should look at raw, as well as standard, scores. After some exploration, consideration of medical issues, as well as consultation with further medical personnel such as the pediatrician or neurologist, or further psychological professionals, such as a neuropsychologist, might be in order.

Achievement Testing

Achievement tests systematically assess past academic learning. Clinicians understand the results are affected by a wide variety of educational opportunities and impacted by a large variety of comorbid conditions. Once disadvantageous conditions such as sensory disorder, intellectual disability, and lack of appropriate/adequate instruction have been ruled out as primary causes of academic difficulties, the academic shortfall has commonly been attributed to processing problems. These can include everything from discrete cognitive functions, such as phonologic processing, to more general mental constructs, such as executive functioning. In fact, good basic processing, the ability to successfully use a wide variety of cognitive strategies in a wide variety of tasks, has commonly been thought to support intellectual level and academic success.

When achievement testing is undertaken along with intellectual and domain-targeted testing, the overall evaluation is commonly referred to as a psychoeducational assessment. The purpose of the assessment is to identify learning problems and usually to rule out other psychological factors that might be complicating learning. In addition, its purpose has been to establish eligibility for services through the public school system under learning disabilities. Clinicians communicating with school systems will need to be aware of the state and local guidelines for establishing learning disabilities and, for example, how/whether/when the kinds of standard testing described here might be relevant under new identification models. However, practitioners will still value standardized (individual) achievement testing as an objective (normative) view of how the child stands nationally and for the ability to identify academic strengths and weaknesses. Of course, other information will be important—for example, the child’s grades, academic interventions, and behavioral information.

Background. Achievement testing is administered to determine a student’s level of functioning in basic academic areas, including reading, mathematics, and writing. Unlike intellectual testing, achievement testing is not necessarily expected to be stable over time because it measures the child’s success in formal learning and is highly dependent on the home environment and the school curriculum.

Assessment. Psychologists commonly begin an assessment of academic achievement by giving a comprehensive test in order to get a sense of a client’s areas of weakness in contrast to their strengths in reading, math, and writing. These findings are compared to school records. Because reading problems are a relatively common reason for referral and their causes are increasingly understood, where indicated, this comprehensive test is commonly followed by other tests of reading skills that separate out accuracy, fluency, and comprehension.

It needs to be noted that while specific learning disabilities (in schools) and specific learning disorders (in clinics) are commonly thought of in terms of underachievement in a specific academic area, learning difficulties can be more diffuse. They might not impact a particular subject in a significant way, but might impact a range of subjects in a moderate way. Or they might impact overall school performance in a drastic way. Under DSM-5, Specific Learning Disorder might be identified with impairments in reading, written expression, or mathematics. As part of the reconceptualization and reorganization of the diagnostic manual around neurodevelopmental disorders, learning problems associated with processing problems impacting general adaptive and social functioning rather than subject areas might be identified as other specified (or unspecified) neurodevelopmental disorder.

COMPREHENSIVE ACHIEVEMENT TESTS. Each of the tests assesses a range of academic areas so that they can be compared to each other within any individual or to academic achievement according to more external standards (age/grade expectations). The Wechsler Individual Achievement Test (WIAT) and the Woodcock–Johnson Tests of Achievement (WJ-ACH) allow for the systematic assessment of reading (basic skills, fluency, and comprehension), mathematics (calculation, fluency, and reasoning), and writing (spelling and brief to extensive composition), as well as other academic spheres. Both instruments are relevant for identifying specific learning disorders in reading, written expression, or mathematics. The WIAT is a companion test to the WISC. The WJ-ACH is a companion instrument to the Woodcock–Johnson Tests of Cognitive Abilities (WJ-COG), which evaluates processing skills and includes measures of intellectual ability, and the Woodcock–Johnson Tests of Oral Language (WJ-OL), which assesses specific oral language functions. As individual achievement tests, both the WIAT and WJ-ACH are widely used in the community and schools. An additional, comprehensive test is the Kaufman Test of Educational Achievement (KTEA), which is co-normed with the Kaufman Assessment Battery for Children (KABC).

OTHER ACHIEVEMENT TESTS. These and additional achievement tests are also available and can involve general or specific assessments.

1. *General achievement tests.* Some instruments focus on screening, such as the basic Wide Range Achievement Test. However, the fourth edition allows for the assessment of sentence comprehension, as well

as reading, spelling, and math calculations. An expanded version provides even more information. There are other tests that may assess a range of academic areas in more depth.

2. *Specific reading tests.* Because of the importance of reading in school and in life, particular effort has gone into systematically assessing reading skills and the ability to make symbolic associations between sights and sounds, as well as the ability to decode words and understand text. In addition to reading subtests on major achievement instruments, there are specific reading tests, such as the Gray Oral Reading Tests (GORT) and the Woodcock Reading Mastery Tests (WRMT). In addition, because of the importance of phonologic awareness in reading, tests of phonologic strengths and weaknesses, such as the Comprehensive Test of Phonological Processing (CTOPP), are also often given. Since achievement tests assess academic functioning in slightly different ways, psychologists often administer a combination of achievement tests to any one client. For example, reading comprehension might be assessed by asking a student to read a passage and supply a missing word or by asking a student to answer questions about a paragraph. How the student does in different contexts may help to explain the nature of their academic problems.

Considerations. Here are several issues that mental health professionals should keep in mind in assessing achievement results:

1. Although estimates vary greatly, it can be realistic to conservatively estimate that between 15% and 30% of children with ADHD have a learning disability, and between 20% and 30% of children with a learning disability also have ADHD. As a result, when a clinician finds one condition, they should look for the other. Although they can co-occur, ADHD and learning disabilities are separate conditions requiring separate and specific recommendations.
2. Most individuals with a learning disability have problems with reading (between 70% and 85%). Students who have learning difficulties in other academic areas commonly also have reading problems. Isolated learning disabilities in mathematics are much less frequent (perhaps 10% to 15%).
3. Although achievement tests commonly note grade- and age-equivalent scores, as well as standard scores, for a variety of reasons, the standard scores are more reliable than the age or grade equivalents.

The concept of grade equivalent can be misleading. For example, it does not mean that a student functioning at the 6.5 level while in the fourth grade could perform sixth-grade work. The score merely indicates that the typical sixth grader would have received the same score had sixth graders taken the fourth-grade test. This same statement would also be true of age-equivalent scores.

4. Although all schools must provide services to individuals identified as disabled, there are other populations who, despite being at an advantage, may still need help but are not protected by federal laws and regulations. Because giftedness is not a disability, it is not defined and covered under IDEA. There is, however, a federal definition of “gifted and talented” referring to high-performance/achievement capability students who need services or activities “not ordinarily provided,” and the federal government encourages their provision through state enrichment (Gifted and Talented Education [GATE]) programs.

Further Assessment. In practice, when any academic problem is extreme or does not respond to appropriate intervention, further evaluation of the problem is in order. Reading problems, in particular, may need very careful evaluation regarding the basic processes that might underlie the difficulty. A language specialist who deals with reading issues or a neuropsychologist who might shed light on the pathways available or impaired in a student can perform this assessment.

Conclusions

A wide variety of intellectual and achievement tests have been explored as they apply to clarifying cognitive functioning in general and describing competencies in the academic and social spheres. There has been some discussion of learning disabilities and disorders and some attempts to provide information so that psychiatrists might help patients receive services through the school as well as in the community. However, the same processing issues that affect academic skills acquisition can affect behavioral control and social appropriateness. In addition to cognitive and neuropsychological testing, more projective testing might be undertaken to help identify the organizational issues that contribute to school or social problems, along with the more emotional factors that might interact with them. A battery of psychological tests provides a fairly systematic assessment of different kinds of input and output as they are affected by more and less structure.

Descriptions and Assessment of Typical Neuropsychological Domains

Typically, in addition to assessing IQ, academic achievement, and social and emotional functioning, neuropsychologists assess domains of memory, attention, executive functioning, language, visual perception, and sensory–motor development. Tests have been developed to examine specific aspects of these domains in isolation so as to increase diagnostic clarity. Although these domains are discussed as different constructs in this subsection, in truth, they overlap with one another in many different ways. For example, the term *working memory* is often conceptualized as being an aspect of attention, as well as a necessary component of good planning (which is part of executive functioning). It is also a component of memory in that when it is not well developed, and it leads to the phenomenon of "forgetfulness." Many of the measures used to discuss one of these constructs will also be used to discuss others. In addition, neural substrates and pathways supporting their functions are often overlapping or, at least, parallel systems.

Thus, the interdependence of these domains is an assumption of this portion of this section. Each subsection provides an overview of the theory supporting the conceptualization of the domains, followed by a description of the ways in which a neuropsychologist might assess them.

Memory

OVERVIEW. To memorize something, a person must first pay attention to it. Assuming that this attention is intact, the next step is to "make" the memory or *encode* it. Once the memory has been made, however, it must be available on demand to be of use. Knowing the name of France's first president is of no benefit if you cannot *retrieve* it during the history examination.

One metaphor for this two-step memory process is a filing cabinet. *Encoding*, then, is when a person puts information into the "filing drawer." Someone with a true amnesic disorder (such as Alzheimer disease) never gets the information into the drawer. No amount of cueing or reminders later will help the person to recall the information because it never "got into the drawer" in the first place. This type of impairment can be seen in some children, most often those with seizure disorders that adversely affect the temporal lobes. For most children, however, the problem described as "poor memory" is actually a difficulty with retrieval. *Retrieval* is the ability to get information out of the "file drawer" once it has been put in. Poor retrieval is associated with problems of organization (the folders are missing labels) and is more often the issue when children are described as being "forgetful."

To differentiate between encoding and retrieval, children are asked to memorize material and then, 20 to 30 minutes later, recall it. If they are unable to remember it spontaneously, the examiner does not know whether they have not encoded it or are having problems with retrieval. If the child can remember the material with cueing (e.g., "In the story I read you, was the boy's name Johnny or Sam?"), retrieval is implicated. For the child who cannot encode, however, cueing will not help.

ASSESSMENT. In assessing memory, several guidelines should be followed. Both visual and verbal memory tasks should be given. Visual memory tasks (such as learning the location of dots or memorizing faces) are usually aided by the right hemisphere. In most people, verbal memory tasks (such as memorizing a shopping list or a story) are supported by the left hemisphere. In addition, the material to be memorized should include rote tasks (such as word lists), as well as material that is presented in context (such as stories). Some memory tasks assess learning or the child's ability to benefit from several presentations of the material. It is expected that, after three exposures to a picture of dots, the child's memory of it will be stronger than it was after the first exposure. If not, encoding may be implicated. A 20- to 30-minute delay should also be part of the memory assessment, and cues should be available to differentiate between encoding and retrieval difficulties.

Other terms in the neuropsychological literature appear to describe memory but are actually probably better classified as part of the attention system. These include *short-term memory* and *working memory*. These terms are discussed in the following subsection on attention.

Attention

OVERVIEW. The attention literature is large and includes many different conceptualizations. The following illustration demonstrates some elements of good attention.

Suppose you arrive at a lecture hall, open your notebook, and rather than scanning the room indiscriminately, turn your attention to the instructor, who is just beginning to speak (*selective attention*). The lecture is mildly interesting, and you are able to pay attention for the full 20-minute presentation (*sustained attention* or *vigilance*). At the same time that you are listening to the instructor, you are taking handwritten notes incorporating headings and subheadings. It appears that you are able simultaneously to listen, write, and organize rather effortlessly, although you are probably shifting your attention among these competing tasks (*divided attention*). A fire engine goes by the lecture hall, and you look up (*distraction*) but are then able to ignore the dimming noise of the siren (*inhibition*) and continue to listen to the lecture (again, *sustained attention*). Suddenly, the fire alarm rings, and you smell smoke. These distracters capture your full attention (*disengagement* from the lecture), and their importance causes you to change your attention and behavior (*set shifting*) as you hurriedly head for the door.

A breakdown in any one of these areas can lead to a breakdown in attention. Some children are so caught up in their private thoughts that they have difficulty disengaging from their inner musings, not realizing, for instance, that their babysitter is asking them a question. Or, once they are involved in a task, they have trouble switching to something new, causing them to “get stuck” or perseverate.

The attention literature also discusses divided attention. This is the ability to pay attention to two things at the same time, although, in fact, a shifting of attention between two things is probably occurring. Good divided attention is important in multitasking. Some authors use the terms *divided attention* and *working memory* synonymously.

ASSESSMENT. Assessment of attention requires a number of approaches. Children with attention problems exhibit them at home and at school whenever a task becomes less interesting to them. They function better when working one on one with a person or when working on a new activity because it is more stimulating. For this reason, the testing environment may not elicit inattentive behavior (especially on the first day). To assess the child’s attention “in real life” and across settings, attention questionnaires should be completed by both parents and teachers. Many researchers consider this aspect of the assessment of attention to be the most important. Some neuropsychological measures have been found to be sensitive to attention as well. Computerized measures of sustained attention that are designed to be long and boring can capture the loss of attention described here. In addition, specific kinds of performance patterns on these measures have been shown to differentiate different types of attention problems.

Assessment of *verbal* short-term memory might include the repetition of digits or of short sentences. Assessment of *visual* short-term memory can be achieved by having the child point to dots or circles on the page in the same order in which the examiner has just pointed to them. Working memory is usually assessed as the second part of a short-term memory test. It requires that the material that has been stored in short-term memory be manipulated in some way. Verbal working memory can be assessed by having the child repeat digits backward or by doing mathematics in their head. Saying the months of the year backward can also assess verbal working memory (as long as the child is able to give them in their usual order without difficulty). Having the child point to the dots on the page in the reverse order in which they are shown can assess visual–spatial working memory.

Executive Functioning

OVERVIEW. Executive functioning could be considered the mature product of good attention. Although not developed in earnest until children reach adolescence, many aspects of executive functioning begin to appear when children are younger and, thus, can be measured. *Executive functioning* refers to the person’s ability to organize their behaviors to perform a specific goal. Good executive functioning allows a person to identify problems, generate solutions, choose among them, follow through on the chosen strategy, and evaluate its effectiveness as the work progresses. Without good executive functioning, children who are bright have difficulty demonstrating their abilities. Their parents often report school underachievement that cannot be explained by learning problems. The issue is not about “knowledge,” but rather the application of that knowledge to everyday functioning.

ASSESSMENT. Assessment of executive functioning requires several tests, given its many facets. Good attention and working memory, already discussed, are crucial to goal-directed behavior. Inhibition can be tested by giving the child a task in which they must control an automatic response. For example, on tests using the Stroop paradigm, the child is shown a color word printed in ink of a different color (e.g., the word “BLUE” written in red ink). The automatic response is to just read the word “BLUE,” but this task requires that the child, instead, name the color of the ink. After several items, inhibition appears to tire, and children with poor impulse control perform worse than their peers.

Fluency can be assessed by having the child generate category words under a time limit. For example, a child might be asked to name as many kinds of toys as they can in 1 minute. A variant of this task requires the child to create as many designs as they can in a 1-minute period, according to strict guidelines.

Cognitive flexibility is often tested with the Wisconsin Card Sorting Test (WCST), a measure of problem solving. On this test, the child is not told how to solve the puzzles; rather, they must use feedback that their attempts are “right” or “wrong” and are then expected to use this information to generate strategies. During the course of this test, the rules often change without warning, requiring that the child “regroup” and develop a new strategy. This measure generates information about the child’s ability to initially figure out the task, their tendency to perseverate on wrong responses, and their ability to use feedback to generate new responses.

Planning is another aspect of executive functioning. Variants of a “tower” test are often used to assess this ability. On a tower test, the child is shown a picture with colored balls or disks stacked on top of one another on wooden pegs in a specific configuration. The child is told to move the balls or disks on the pegs on an actual model on the table to match the configuration shown in the picture. The child is instructed to move only one ball or disk at a time and to use as few moves as possible. To perform the task well, the child must first “hold back” and not make impulsive moves that may get them “cornered.” The child must also visualize the first few steps of the problem. Thus, both impulse control and visual working memory are required to exhibit good planning on this rather entertaining test.

Language

OVERVIEW. Human language organizes, supports, and communicates knowledge, memories, and ideas. Beyond just allowing people to communicate with others, language organizes both thoughts and emotions, as well as helps people sequence their actions. Although traditionally discussed in terms of left hemisphere functioning, much of the human cortex is involved in various aspects of language. Communication includes both *speech*, the rapid and complex motor movements involved in talking, and *language*, the code used to express thoughts and ideas.

In considering language, perhaps the most common distinction made is between *expressive* and *receptive* language. Expressive language requires the production of language, including articulating clearly, finding the right word, and applying grammar and syntax to one's ideas, in addition to vocal fluency and voice tone (prosody). Receptive language involves the ability to comprehend and remember what is said.

Children with expressive language problems may appear to have little to say and are considered to be shy. In fact, however, their difficulty may be with self-expression. Some children who are very talkative ("fluent") may also have difficulty with finding the word they want or organizing their sentences to make them clear. The paradox of a fluent child with an expressive language disorder may cause their problems to be overlooked.

Receptive language, or the ability to understand what is being said, represents another aspect of the language system. Children with poor receptive language have difficulty in processing information that is spoken to them and may have difficulty learning in the classroom or appear to be inattentive. Sometimes they appear to be oppositional because of their difficulty with understanding (and therefore *doing*) what they are told.

Secondary problems of children with language disorders include difficulties with social interactions and processing of emotions. Language is what humans use to interact and communicate their ideas to one another. When this ability is compromised, children may isolate or try to find less language-intense activities to occupy their time. Emotional problems may ensue from the child's difficulty with using language to express and, therefore, process their inner world.

ASSESSMENT. Assessment of language should include several measures meant to identify the child's specific language profile. Tests should assess all levels of language, including phonemes, single words, simple phrases, complex sentences, and conversation. Measures of both expressive and receptive language should be included. In the assessment of receptive language, children are asked to distinguish between similar sounds and words, remember and repeat word lists and related strings of words, point to a picture that depicts a vocabulary word, and follow increasingly complex directions presented only once. In the assessment of expressive language, children are asked to perform tasks such as listing as many round objects as they can within a time limit, naming a depicted or described item, defining words or concepts, or creating a syntactically complex sentence according to strict guidelines.

In addition, the psychologist might explore *pragmatics*, which is the child's ability to participate in a conversation and use social language. This involves interpreting nonverbal aspects of communication, as well as observing basic social rules, such as turn taking in conversation. Although neuropsychologists often evaluate pragmatics in addition to receptive and expressive language, they also work in concert with speech and language specialists when additional assessment is indicated.

Visuoperceptual Functioning

OVERVIEW. There are several associated constructs in neuropsychology that reflect people's ability to make sense of what they see, to organize it, or to copy it. These abilities are referred to as *visuoperceptual–visuoconstructive abilities*.

Problems with *visuoperception* are distinct from problems with vision. A person with acute eyesight can struggle with perceptual difficulties, such as identifying which of several figures are exactly alike. Some children have difficulty seeing exactly where something is, and these children may have trouble localizing a point in space or judging the direction of a line. *Visuoconstruction* abilities allow a child to join parts to make a whole. These skills require the integration of the motor system with the visual system. Examples include the ability to put together blocks to form a design or to draw three lines to form a triangle.

Problems with visuoperceptual development have academic, as well as social, ramifications. Academic areas, such as mathematics that are less reliant on verbal support are at risk. In addition, concepts such as time and monetary values may not be clearly understood. Students with these difficulties often exhibit a poor sense of direction, and problems with integrating complex visual arrays may lead to feelings of being overwhelmed. They may also have difficulty “reading between the lines,” thereby making comprehension of less tangible reading concepts (such as theme) more elusive.

Social problems are also often seen in students with these delays. Many elements of good social interactions are nonverbal, including the ability to notice and interpret gestures, facial expression, body posture, and tone of voice. Students with visuoperceptual delays may be overreliant on verbal information and may not understand when people are being sarcastic or when something is said in jest.

ASSESSMENT. Assessment of visual processing must address each of the specific elements of this system. The visuoperceptual abilities should be tested using tasks that do not require the child to use their hands to produce the response—for example, activities that require the child to identify designs that match or differ from the target, as well as measures of mental rotation (finding which design one is the same as the target, only rotated). Visuoconstruction tasks add the demand of integrating the hands and eyes in producing the response—for example, having the child draw copies of designs or use blocks to create a replica of a model.

Sensory/Motor Functioning

OVERVIEW. The sensory/motor system is also assessed as part of the neuropsychological examination. Lateralized sensory or motor problems suggest neurologic problems on the opposite side of the brain and are often correlated with cognitive processes localized to the right or left hemisphere. Tasks requiring the perception of visual/auditory fields or specific actions with the right and/or left sides of the body are part of this domain. In addition, the integration of perceptions or movements is also assessed.

Motor assessment is further broken down into the assessment of handedness and tests of large versus fine motor development, as well as the ability to plan motor responses (praxis).

ASSESSMENT. The sensory examination usually includes an assessment of visual fields using clinical methods such as having the child look at the examiner’s nose and then determine whether the assessor is moving the right or left extended hand. Similarly, the assessment of bilateral auditory perception might include the assessor standing behind the child and rubbing their fingers near the child’s right or left ear. Other perceptual tests might assess the ability to name unseen objects placed in the child’s right or left hands. Finger agnosia is tested by touching a finger when the child’s hand is hidden behind a screen and then having them indicate which finger was touched. Integration of perception might include having the child follow directions involving a picture that is shown. Age-based normative data are available for all of these tasks.

Both fine and large motor tests are usually assessed on both the right and left sides of the body. Lateralized fine motor tasks include quickly placing pegs in holes with each hand or squeezing a hand dynamometer with each hand to assess grip strength. Fingertip tapping is one way of testing motor sequencing, as do activities requiring the child to repeat sequences of movements from memory. Handedness is best assessed by having the child do a number of tasks with one hand (e.g., “Show me how you use this spoon,” “Hand me the dime,” and “Throw me the ball”) in random order. Assessment of difficulties with motor planning can be done using pantomime.

Large motor testing involves having the child demonstrate gait while walking forward and backward, running, skipping, walking a straight line, and balancing on one foot. In cases in which the findings of motor screening are significant, the neuropsychologist might refer the child to an occupational or physical therapist for further, more specific, evaluation.

NEUROPSYCHOLOGICAL CONCLUSIONS

Neuropsychological testing is commonly undertaken according to several discrete domains that reflect areas of brain functioning. Typically, these include attention and executive functioning, memory, and language, as well as visuoperceptual and sensory/motor functioning.

Considerations

In considering neuropsychological issues, the following factors should be kept in mind:

1. Although it is always tempting to think in terms of organic versus functional, it needs to be remembered that these are interacting systems, and learning new skills can alter brain structure. This has

been found in the case of taxi drivers in a major European city, as well as in individuals being taught to juggle.

2. It should be noted that the term “attentional problems” can be used diagnostically or descriptively. The fact that clinicians detect problems with attention on a student’s individual intellectual or processing tests (including computerized instruments) does not mean that the student has ADHD. Under DSM-5 and DSM-5-TR, this is a clinical diagnosis that involves specific criteria, is described behaviorally (inattention, hyperactivity, and impulsivity), and is determined by history (several symptoms by age 12 years) and current functioning (several symptoms seen in two settings). Systematic assessment can help to clarify issues around ADHD (and medication), but this will not be done with a single instrument and will require a pattern of responding on a selected group of tools along with interviews, observations, and, usually, rating scales from home and school.
3. It should be noted that learning (and emotional) problems can mimic attention deficit. In assessing ADHD, the clinician will need to rule out artifacts and to consider whether a child stops paying attention because they stop understanding (e.g., what they are reading or hearing) or have primary ADHD. In addition, the clinician will need to consider whether something like ongoing depression or situational anxiety is making it hard for the child to attend.
4. Broad constructs such as executive function can have relevance for a wide variety of diagnostic categories, such as ADHD and ASD. It is possible that about one-third of the adults and children who have ADHD also have executive dysfunction (EDF), which can increase the difficulties facing these clients. As a result, as with ADHD and learning disorder, where there is a large overlap when one sees ADHD, one might look for EDF. The statistical overlap between ASD and EDF is harder to determine because of issues of definition as well as research results. Depending on how it is measured, EDF might be seen as ubiquitous in ASD.
5. After early brain injury, language and motor functioning are the most likely to benefit from “plasticity.” Some research suggests that, with this process of reorganization, other functions (most notably, visuoperceptual abilities) may be “crowded out,” yielding scores that are lower than expected.
6. Interventions for neurologically driven developmental delays have their most profound effect on younger children. Recent studies have shown

that, in children with reading disabilities, bilateral representation of language identified with fMRI before intervention shifted to the left hemisphere by several orders of magnitude in every subject after only 80 hours of reading intervention. These changes in the brain were accompanied by improved reading skills. Thus, the philosophy of delaying intervention until a deficit is fully expressed may keep children from receiving the full benefit that early intervention provides.

7. Risk factors for reading disabilities include family history, early language delays, poor articulation, chronic ear infections, poor early rhyming abilities, inability to recite (not sing) the alphabet by the end of kindergarten, and early brain injury.
8. “Ambidexterity” (consistently using the right hand for some specific tasks and the left hand for other specific tasks) often runs in families in which several members are left handed. In contrast, “ambiguous handedness” (or the use of either hand for the same task; sometimes writing with the right hand, sometimes writing with the left hand) can be a pathognomonic sign suggesting poor cerebral organization for specific behaviors.
9. ADHD more adversely affects abilities typically associated with right hemisphere functioning (such as fine motor skills and visuoperceptual abilities) and affects attention and executive functioning. Psychostimulant medication has been shown to improve functioning in all of these domains in children with ADHD.

DIFFERENT APPROACHES

Psychoeducational, psychodiagnostics, and focused neuropsychological assessment represent different paradigms: The first assesses referral issues in a descriptive way without reference to brain–behavior relationships, and the last assesses them in a functional way from a brain–behavior point of view. In general, when a systematic assessment of brain–behavior relationships is important to understanding referral issues, focused neuropsychological evaluation is indicated. When the referral question centers around learning and school performance, a psychoeducational assessment would be relevant and useful. However, every situation should be decided on a case-by-case basis, in consultation with the parents and involved professionals. It should be noted that developmental, psychoeducational, or psychodiagnostics evaluations and focused neuropsychological assessment are complementary rather than competing approaches. They can be used as alternatives, depending on the needs of the case, or to supplement each other in complicated situations involving testing by one or more professional psychologists. However, regardless of the type of assessment, it is the psychologist's ability to integrate these and other test data with clinical observations, referral issues, and diagnostic possibilities that benefit the patient in a practical way in terms of understanding what is going wrong and making appropriate interventions.

35.4 Psychiatric Emergencies in Children and Adolescents

ALEXANDRA JUNEWICZ, M.D., AND RUTH S. GERSON, M.D.

The past 20 years have seen a dramatic increase in the number of visits to emergency departments (EDs) by children and adolescents in psychiatric crisis, with estimates now reaching 2% to 5% of all visits or over 800,000 visits per year. Between 2007 and 2016, the number of pediatric emergency visits for mental health disorders rose by 60%. Unfortunately, appropriate assessment and treatment are not available to many youths presenting to the ED in a psychiatric crisis. Many present to EDs with limited or no pediatric or mental health clinicians. Nationwide, fewer than 20% of youth presenting to the ED in psychiatric crisis are seen by a mental health professional, and fewer than 50% of youth presenting to the ED with suicidal behavior receive a mental health evaluation, even though those who do not are at increased risk of a future suicide attempt. As the ED is the entry point to psychiatric care for greater than half of youth, improving the care provided to these patients is imperative. This section will underscore the key components of the emergency evaluation of a child or adolescent in a psychiatric crisis and will emphasize the following:

- Understanding the role of developmental, academic, and social context in assessing children in psychiatric crisis
- Differential diagnosis of behavioral disturbances
- Assessment of suicidality, aggression, new-onset psychotic symptoms, and risk-taking behaviors
- Assessment of nonverbal children (including young children and those with autism or intellectual disability [ID])
- Management of agitation in the ED
- Legal issues in emergency child psychiatry, including assessing for child abuse

EPIDEMIOLOGY

The emergency care system has unfortunately been slow to adapt to the increasing demand for child and adolescent psychiatric care. Youth in psychiatric crisis are difficult for EDs to manage. Most children presenting to EDs in psychiatric crisis are seen in general medical or pediatric emergency rooms or, more rarely, in adult psychiatric emergency services (PES). Most EDs lack the specialized staff (child psychiatrists, psychologists, social workers, and nursing staff) necessary to effectively care for youth in psychiatric crisis, who also have a longer length of stay and increased need for inpatient admission or transfer than other youth. EDs also typically lack the physical resources to manage the high volume of child psychiatric patients safely. Agitated or suicidal youth are often placed together in medical examination rooms full of potentially dangerous objects, in busy and noisy holding areas, or on stretchers in trauma bays with security or police supervision. Youths who are seen in the adult PES instead are exposed to adult patients who are severely mentally ill, homeless, or intoxicated. This can be frightening and reinforces the stigma surrounding mental illness and psychiatric treatment. The PES also lacks appropriate staff, as adult psychiatrists and nursing staff trained to work with adults may not know how to approach youth in a developmentally appropriate way.

Youth seeking emergency psychiatric care are frequently clinically acute and clinically complex. Many have previously undiagnosed or undetected psychiatric illness including depression, anxiety, psychosis, post-traumatic stress disorder (PTSD), substance use, autism, and attention deficit hyperactivity disorder (ADHD). Suicidal thoughts and severe aggression are also common precipitants for an ED visit, again often subsequent to a lengthy period of unrecognized or untreated psychiatric symptoms. Suicide is currently the second leading cause of death for 10 to 24 year olds, and as many as 10% of children attempt suicide sometime during their young lives. Studies indicate that 40% of youth who attempt suicide had been seen in the ED in the year before their death, suggesting that an opportunity for life-saving intervention at that ED visit was missed. EDs are also increasingly seeing violent youth, who are often “frequent fliers” in the ED. They frequently have diagnoses of conduct disorder or other disruptive behavior disorders; are involved with the juvenile justice or child welfare systems; and have cognitive impairments that make it difficult for them to function in the community. Many youths present with such severe symptoms that inpatient hospitalization is required. But with the steady decline in access to inpatient child and adolescent psychiatry beds, 23% to 58% of youth in need of psychiatric hospitalization are left boarding in EDs for days, without meaningful treatment, awaiting inpatient admission.

There are significant racial and ethnic disparities among children and adolescents who experience psychiatric crises. While ED visits for mental health complaints have been rising among all youth, minority youth have been disproportionately affected by this trend. Rates of mental health–related ED visits are highest among non-Hispanic Black youth and have been increasing at a greater rate among Hispanic youth. Although suicide rates have traditionally been higher among White than Black individuals, suicide rates have been steadily increasing among Black youth for more than two decades. In recent years, suicide rates have risen for Black youth aged 5 to 11 years while decreasing for their White counterparts. Currently, among children younger than 13 years of age, the suicide rate for Black children is two times higher than the rate for White children. Disparities also exist among other racial, ethnic, and sexual minority groups. For instance, American Indians, Alaska Natives, and lesbian, gay, bisexual, transgender, and questioning or queer (LGBTQ) youth have a higher risk for suicidal ideation and behavior. Despite these data and trends, minority youth area are less likely to have access to mental health treatment and services than nonminority youth. Consequently, minority youth may be more likely to suffer from undetected and untreated psychiatric symptoms, which may worsen to the point of crisis.

Despite the well-documented demand for emergency mental health care, many training programs lack comprehensive instruction on emergency psychiatric assessment of youth. This chapter will outline the key priorities, principles, and components of a comprehensive evaluation and risk assessment for a child or adolescent in psychiatric crisis.

PRIORITIES OF EMERGENCY PSYCHIATRIC EVALUATION FOR CHILDREN AND ADOLESCENTS

Safety

The psychiatric evaluation of a child or adolescent in the ED should have two main priorities: safety in the ED (for patients and staff) and effective clinical and risk assessment to determine whether the child is safe to leave the ED. Ensuring safety in the ED starts with appropriate physical space. Children and teens presenting to the ED with suicidal ideation, aggressive agitation, or other acute psychiatric manifestations are unlikely to be safe in a standard medical examination room. The ED environment, whenever possible, should be modified for safety including removing potentially dangerous items, decreasing overstimulation by avoiding bright lights and unnecessary noise, providing privacy while allowing the patient to be observed continuously, and enhancing patient comfort by giving the patient a comfortable place to lie or sit down as well as food or drink. The child and family should be given clear expectations as to the components of the evaluation, the waiting time, and the interventions and consequences that will be given should the patient become agitated or violent. Adequately trained personnel should be available to help if the patient becomes agitated, and staff should have a clear response plan for calming an agitated or aggressive patient including with medication or restraint if needed (this is discussed further below). These modifications reduce the likelihood of aggression to self or others, and if such aggression does occur, mitigate the risk of serious injury to patient or staff.

Evaluating Medical and Psychosocial Causes of Behavioral Disturbance

The second priority of the ED evaluation, effective clinical and risk assessment, starts with ruling out and treating medical and social/systemic causes of the behavioral disturbance. While children and adolescents generally lack the complex and chronic medical conditions of adult psychiatric patients, medical illness can nonetheless masquerade as a psychiatric illness in subtle and confusing ways. Seizures (particularly temporal lobe seizures and absence seizures), infectious and autoimmune encephalitis, brain tumors, head trauma, and tropical diseases can manifest with hallucinations, mental status change, and behavioral dysregulation. Children may also present with behavioral changes related to undiagnosed chronic diseases such as porphyria, sickle cell anemia, metabolic disorders, and other genetic syndromes. Drug intoxication and other self-poisoning (due to accidental ingestion or intentional acts meant as a suicide attempt or to get high) can also present with psychiatric symptoms. Red flags that are suggestive of a possible medical etiology include the following:

- Clouding of consciousness
- Waxing and waning mental status
- Disorientation
- Memory impairment
- Acute onset of psychosis in a child with no previous psychiatric history
- Abnormal vital signs

When a medical etiology is suspected, even if it is unlikely, an appropriate workup (including neuroimaging when indicated, and cerebrospinal fluid studies if encephalitis is a potential concern) should be completed to ensure that a medical illness is not missed. Even if a youth has already been “medically cleared,” further assessment may be needed as the goal of the medical clearance is not to “rule out” all possible medical etiologies. Youth without suspicion for medical etiology of psychiatric symptoms should receive a focused medical assessment, and testing should be incorporated judiciously. Children who have acute medical illness, who are severely intoxicated, or who have made a suicide attempt by overdose or other method that has caused significant injury, will likely require medical admission prior to psychiatric hospitalization, and should be followed by the psychiatric consult–liaison service during their medical care to avoid unnecessary delay in their psychiatric treatment.

Clinicians should also remember that normal developmental changes, such as puberty, and minor physical ailments such as ear infections, tooth pain, hunger, or fatigue can manifest with or trigger psychiatric or behavioral symptoms, particularly in young children and youth with intellectual or developmental disabilities (Table 35.4–1).

While medical illness can and does masquerade as psychiatric illness, what is even more common in children is psychosocial crisis manifesting as psychiatric disturbance. It is crucial to consider when a child presents with behavioral disturbance or even more classically psychiatric symptoms such as hallucinations or anxiety, that the child may be the “identified patient” in a distressed or pathologic family or social system. Domestic violence and family conflict often manifests with aggressive behavior in a child; reports of auditory hallucinations may be a child’s mimicking the symptoms of a mentally ill parent; or the child may be a victim of physical or sexual abuse or of fabricated or exaggerated symptoms in cases of medical child abuse. Treating the child alone when the source of the symptoms is in the family or social environment not only puts the child at risk for adverse effects from unnecessary medication, but is also psychologically damaging as it teaches the child that they are the problem, not the toxic context in which they find themselves. Alternatively, the child may have true psychiatric illness, but the emergency is not a worsening of symptoms per se but rather that the caretakers are for whatever reason less able to manage those symptoms. A parent may be weakened by illness, divorce, or financial stress, or may lose a key support or structure like an after-school program or grandparent willing to help care for the child; or the child may be removed from the parent and placed in a foster care home where the caretaker is not equipped to care for a child with mental illness. Here, again, the crisis is not psychiatric per se, but rather a breakdown of the caretaking system, which must be shored up if the child is to be discharged safely.

Table 35.4–1.
Common Medical Causes of Psychiatric Disturbance in Children and Adolescents

Fever
Nonconvulsive status epilepticus
Temporal lobe seizures
Absence seizure
Encephalitis
Central nervous system neoplasm or other occult malignancy
Cerebral systemic lupus erythematosus
Childhood confusional migraine
Head trauma or postconcussive syndrome
Porphyria
Sickle cell disease
Substance intoxication
Withdrawal from illicit substances
Anticholinergic delirium
Steroid psychosis or steroid-induced mania
Medication adverse effects such as akathisia from risperidone or irritability from levetiracetam

PRINCIPLES OF EMERGENCY PSYCHIATRIC CARE FOR CHILDREN AND ADOLESCENTS

Comprehensive Assessment of the Child

When a patient is in crisis, treatment must start immediately, so the initial assessment must be therapeutic in itself. Each piece of the assessment is directed toward understanding the nature of the crisis, de-escalating and mitigating the distress of the child and accompanying adults, and monitoring response to therapeutic information. The first step is information gathering. Given the case complexity of youth presenting to the ED in psychiatric crisis, collateral from the parent or guardian and any accompanying adults is a critical source of information about the child's life at home and at school, their strengths, stressors, medical issues and history (including allergies), history of psychiatric treatment (including response and compliance), developmental history, history of substance use, family history, legal history, social history including any prior trauma exposure, and academic history. Parents or accompanying adults will also have a perspective on the current crisis; however, the assessment should not be based exclusively on the parent or guardian's report, even if the child is very young or intellectually disabled. A curious, empathic interview of the child is imperative to understand their perspective, the reasons behind their behaviors, their interpretation of what is going on around them, their strengths and cognitive abilities, and the internalizing symptoms such as depression, anxiety, and trauma-related symptoms that often are missed by parents and other adults (Table 35.4–2).

Table 35.4–2.
Components of a Comprehensive Assessment

Identifying information
Chief complaint
History of present illness
Past psychiatric history
Current medications and medication history
Past medical history
Substance use history
Trauma history
Social history including trauma and child welfare involvement
Developmental and educational history
Family history
Legal history
Mental status examination including cognitive screen
Medical clearance including physical if indicated

Conducting the interview with an aim to truly understand and empathize with the child's perspective can make it very therapeutic for the child. Most children have not had the experience of an adult truly listening to them, striving to understand their experience without judgment or reprimand, and trying to help them. Explaining the purpose of the evaluation and the clinician’s role and decision-making process in a clear, direct manner fosters rapport with children, alleviates their sense of helplessness, and promotes their sense of agency. The child’s privacy should be respected and the confidential nature of the evaluation (and the limits of confidentiality) should be made clear. While a conversational rather than “checklist” approach is preferred, the interview with the child must include questioning about suicidal and homicidal ideation, though with the recognition that children and adolescents often minimize or deny suicidal or homicidal ideation or intent, as they fear getting in trouble or being hospitalized. An empathic, normalizing, and nonjudgmental stance to these questions can increase the likelihood of an honest response and also serves to build rapport, even with hostile adolescents. Questions about hallucinations and delusions are also critical, though the clinician should be careful with phrasing these questions as young children or those with developmental delays may misinterpret the question (or their own internal experience) and falsely answer yes, while teens who are truly psychotic may deny such symptoms for fear of being labeled as “crazy.”

For very young or otherwise minimally verbal or nonverbal children (such as those with autism or ID), the clinician should still attempt to engage the patient to complete a thorough mental status examination. A child with little expressive language may still be able to follow commands, engage in parallel or reciprocal play, and express needs through gestures. The clinician can also observe the child’s fine and gross motor skills through drawing and playing, and can assess frustration tolerance, hyperactivity, distractibility, attachment to the parent or guardian (or evidence of fear of the parent), and anxiety with separation.

A therapeutic stance is equally important for interviewing parents, foster parents, and other caregivers, who are often exhausted from dealing with frightening and disruptive symptoms and behaviors without a good understanding of their cause. Treating child psychiatric patients in the ED often feels like having two patients—the child and the family—and approaching both carefully and empathically is crucial to understand the situation and create buy-in for ongoing treatment. A parent’s anxiety or agitation can be ameliorated by empathizing with how difficult a child’s mental illness can be for a family and acknowledging that the ED evaluation itself is a difficult process. Reducing the parent's anxiety or anger helps them to reflect on and mentalize the child's experience and to consider their own important role in treatment. Interviews with both the parent and the child should be conducted in a quiet, private space free from interruption so that everyone feels safe and respected when discussing their challenges and expressing painful feelings.

In many cases, a child will be brought to the ED by someone other than their parent (e.g., police, emergency medical services [EMS], friends, or child welfare workers). If the parent or guardian cannot be reached, most states allow clinicians in an emergency to initiate evaluation and treatment of the child, though ongoing attempts to reach the parent should be made. Occasionally, an adolescent will insist that the parent not be contacted. While many states allow adolescents to seek mental health services without the parent being involved or notified, these youth should be encouraged to include their parents in the evaluation, and often with support and empathy of the ED staff, a rapprochement can be made between the parent and child.

Often the ED clinician will find that the descriptions of symptoms and behaviors and the explanations for such will vary between the child, the parent, and the other informants. These differences may stem from real differences in the child's symptoms and behaviors across different contexts (e.g., at home or at school). Alternatively, a parent or other adult may not be aware of or attuned to the child's internal state and thus may miss internalizing symptoms and overemphasize externalizing behaviors. The child may have poor insight, may be guarded or minimizing of symptoms, or alternatively may be voicing a major stressor (such as abuse, domestic violence, or school bullying) that the adults are attempting to hide or of which they are unaware. Other sources of information may be needed to obtain a balanced view of the child and family system. A child's teachers, outpatient providers, pediatrician, and social services workers (child welfare workers, other case managers) can provide very helpful perspective on the child's recent symptoms and functioning, his developmental and cognitive level, the family's strengths and vulnerabilities, and the resources and supports available to them in the community. Consent from the parent or guardian should ideally be obtained before contacting any of these individuals, but in potentially life-threatening situations such as suicidal ideation or concern for child abuse, the safety of the patient outweighs the risk of confidentiality, and the clinician can contact these individuals for information without violating the requirements of Health Insurance Portability and Accountability Act (HIPAA).

Trauma-Informed Assessment and Care

The ED clinician's key task is to integrate the child's presentation and collateral information into a clear formulation and effective treatment plan. This must include consideration of trauma, as unfortunately traumatic experiences are highly common in youth presenting to EDs with psychiatric emergencies. High rates of trauma and abuse (over 50%) and child welfare involvement (over 30%) have been documented in this population. ED clinicians should thus utilize a trauma-informed approach to care. Clinicians should inquire about a child's history of trauma with empathy, respect, and calm. Validation, normalization, offering genuine praise, and highlighting resiliency may help a child speak about and process traumatic events. It is important to inquire directly about traumatic experiences but also to recognize that youth exposed to trauma may not disclose it, due to explicit or implicit messages from family members or others about not disclosing, fear of not being believed, or PTSD-related avoidance. Thus "universal trauma precautions" are often recommended.

While it is often difficult to ascertain whether acute psychiatric symptoms displayed by a child in an ED stem from having been traumatized, even if a child's psychiatric symptoms predated traumatic events, it is highly likely that these events exacerbated their symptoms. The ED visit can be an important opportunity for psychoeducation and reframing symptoms in a trauma context with youth and caregivers. Clinicians should remember that their words are powerful, as they can shape the manner in which the child views themself and the way others view the child. Focusing on a child's strengths can be therapeutic and foster agency, resilience, and engagement.

Effective Psychotherapeutic and Psychopharmacologic Management of Agitation

Importantly, the ED visit and interactions with clinicians should not add to a child's trauma history. Key to ensuring that the evaluation is therapeutic is the prevention and effective management of agitation to avoid restraint and seclusion. Children and adolescents experience restraint and seclusion as frightening, and their perception of time can become distorted, such that they perceive themselves as being restrained for much longer than it is in reality. After a restraint, children are angry at and frightened of staff, which will profoundly limit the staff's ability to fully assess and treat them. Restraint can be avoided through proactive engagement to prevent a crisis and by effective verbal and psychopharmacologic de-escalation strategies.

A safe environment is the first step to prevent agitation. Overcrowding, excessive noise, lack of privacy, long wait times, and a tense atmosphere can agitate even a normally quiet child. For a child with impulse control problems, psychosis, trauma history, or autism, such a setting can be catastrophic. A safe ED environment, attention to who is at risk of agitation, vigilance to early signs of distress, and preventive strategies can avert a crisis. When a child is showing early signs of agitation, the ED staff should work as a team to de-escalate the situation. First, the patient should be moved to a safe and quiet area, if they are not already there, separated from other patients and either separated from or rejoined with preferred family members based on the patient's preference. The patient should be offered food, drink, and distractions such as TV or a game. Choices (of food or drink or TV channel) can help a child feel more in control and thus regain emotional control. One member of the staff should approach the patient in a nonthreatening way to listen to their complaint or concern, direct them away from the focus of their anger, and encourage them to verbalize their needs. If the child begins to explain their concern, even if they are still agitated or yelling, staff should empathize by repeating their statement or paraphrasing it back to ensure that the patient's view is understood correctly. As the child makes incremental steps to calm down, for example, by talking to staff or by refraining from pacing, staff should praise these positive steps even if the child is still engaging in other negative behaviors (such as cursing or scowling). Most children in the ED are anxious about the process, their parents' reaction, and the possibility of hospitalization. Others may be paranoid, may have been abused and thus be hyperreactive to perceived threats, or may be hungry or in pain. Staff should work empathically to alleviate distress, while demonstrating calm and clarity that they will work to keep the patient and all others safe and that violence will not be tolerated.

A child's agitation can also stem from a parent's anxiety, anger, or fear. Parents can be anxious in the ED because of concerns about the child's symptoms or safety, fear that the child will be taken away from them (by child protection or by hospitalization), or worry about missing work or affording the cost of the emergency evaluation or ambulance. They may have themselves had negative experiences with psychiatric care. The team must listen to and empathize with the parent, emphasize that the parent is not being blamed for the situation, and assure them that the staff will work with the family to ensure the child's safety. If a parent is agitated, it is most often helpful to separate the parent and the child while staff work to calm the parent, to avoid the child becoming agitated as well.

If the patient continues to be agitated and begins to escalate further, perhaps making threats or beginning to destroy ED property or attempting to elope, oral medications should be offered. The medication should target the underlying cause of the agitation and should be uniquely tailored to the child's individual needs with regards to route of administration, potential side effects, comorbid physical illness, and past experience with PRN medications. Medication should be selected to sufficiently calm, but not sedate, the child. There is no firm evidence or consensus that one medication or even a certain class of medications is preferable to another in managing agitation. Rather, potential adverse effects should be carefully weighed against potential benefits while considering a child's age, size, recent medication administration, medical conditions, and the psychological cause of their agitation. Medications should be chosen carefully, as the medications most commonly used for agitation in adults can have significant adverse effects on children. The potential for harm from medication is significant, and particularly ketamine, barbiturates, and opioid analgesics are strongly not recommended in this population.

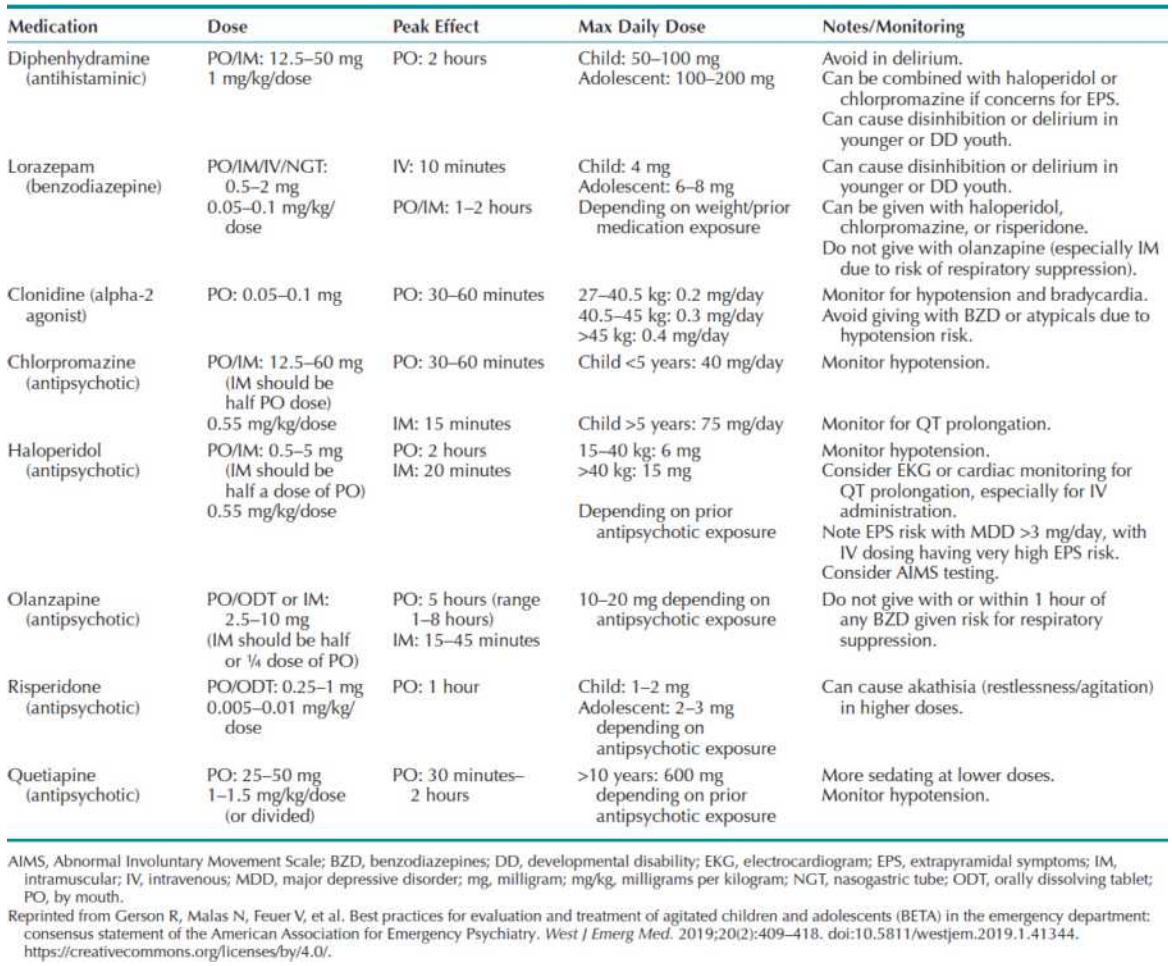
Oral medication should always be offered before injectable medication (IM), particularly because many children (even ostensibly tough ones) are afraid of needles and can become more agitated when approached with an injection. Administering an injection will require a physical hold or restraint, with a high potential for injury to staff and children. A child who initially refuses an oral medication may accept the oral medication if offered the choice between oral and IM. This not only allows the patient to avoid the potentially traumatic experience of restraint and IM but also allows the child to make a choice and begin to demonstrate self-control (Table 35.4–3).

If all the above techniques to de-escalate an agitated child have failed, and the child continues to refuse oral medication and engage in violent or dangerous behaviors, an IM may be indicated for acute chemical restraint.

Care should be taken regarding dosing, as most medications are more potent (and thus require lower dose) when administered intramuscularly.

In most cases, when IM is required, a physical hold, restraint, or seclusion is also necessary for safety. The choice of intervention (physical hold, restraint, or seclusion) should be made based on the regulatory standards of the Center for Medicare and Medicaid Services and The Joint Commission on Accreditation of Healthcare Organizations, state and local governmental and oversight agencies, and the policies of the hospital, as well as the individual patient history. For example, for a child who has been sexually abused, restraint may be deeply retraumatizing such that seclusion should be chosen instead; a child who is engaging in self-injury may not be able to be safe in seclusion and thus restraint may be more therapeutic. The physician should ensure that the child is safe, physically comfortable, and medically stable in the restraint or seclusion, and should explain to the child the reason for the restraint or seclusion and that they will be released as soon as they can be safe. Regulation and hospital policy will dictate the allowed duration of restraint or seclusion, but regardless of regulation the child should be removed from restraint or seclusion as soon as possible. Once the child is released, his safe behaviors should be praised, and the physician should debrief with the patient to review what upsets the patient and how such episodes can be avoided. While restraints and seclusion can be traumatizing for children if executed poorly, with appropriate support, explanation, and debriefing, it can be an opportunity for the youth to better express his feelings and understand the roots of his behavioral dyscontrol.

Table 35.4–3. Medications for Agitation



Medication	Dose	Peak Effect	Max Daily Dose	Notes/Monitoring
Diphenhydramine (antihistaminic)	PO/IM: 12.5–50 mg 1 mg/kg/dose	PO: 2 hours	Child: 50–100 mg Adolescent: 100–200 mg	Avoid in delirium. Can be combined with haloperidol or chlorpromazine if concerns for EPS. Can cause disinhibition or delirium in younger or DD youth.
Lorazepam (benzodiazepine)	PO/IM/IV/NGT: 0.5–2 mg 0.05–0.1 mg/kg/dose	IV: 10 minutes PO/IM: 1–2 hours	Child: 4 mg Adolescent: 6–8 mg Depending on weight/prior medication exposure	Can cause disinhibition or delirium in younger or DD youth. Can be given with haloperidol, chlorpromazine, or risperidone. Do not give with olanzapine (especially IM due to risk of respiratory suppression).
Clonidine (alpha-2 agonist)	PO: 0.05–0.1 mg	PO: 30–60 minutes	27–40.5 kg: 0.2 mg/day 40.5–45 kg: 0.3 mg/day >45 kg: 0.4 mg/day	Monitor for hypotension and bradycardia. Avoid giving with BZD or atypicals due to hypotension risk.
Chlorpromazine (antipsychotic)	PO/IM: 12.5–60 mg (IM should be half PO dose) 0.55 mg/kg/dose	PO: 30–60 minutes IM: 15 minutes	Child <5 years: 40 mg/day Child >5 years: 75 mg/day	Monitor hypotension. Monitor for QT prolongation.
Haloperidol (antipsychotic)	PO/IM: 0.5–5 mg (IM should be half a dose of PO) 0.55 mg/kg/dose	PO: 2 hours IM: 20 minutes	15–40 kg: 6 mg >40 kg: 15 mg Depending on prior antipsychotic exposure	Monitor hypotension. Consider EKG or cardiac monitoring for QT prolongation, especially for IV administration. Note EPS risk with MDD >3 mg/day, with IV dosing having very high EPS risk. Consider AIMS testing.
Olanzapine (antipsychotic)	PO/ODT or IM: 2.5–10 mg (IM should be half or ¼ dose of PO)	PO: 5 hours (range 1–8 hours) IM: 15–45 minutes	10–20 mg depending on antipsychotic exposure	Do not give with or within 1 hour of any BZD given risk for respiratory suppression.
Risperidone (antipsychotic)	PO/ODT: 0.25–1 mg 0.005–0.01 mg/kg/dose	PO: 1 hour	Child: 1–2 mg Adolescent: 2–3 mg depending on antipsychotic exposure	Can cause akathisia (restlessness/agitation) in higher doses.
Quetiapine (antipsychotic)	PO: 25–50 mg 1–1.5 mg/kg/dose (or divided)	PO: 30 minutes–2 hours	>10 years: 600 mg depending on prior antipsychotic exposure	More sedating at lower doses. Monitor hypotension.

AIMS, Abnormal Involuntary Movement Scale; BZD, benzodiazepines; DD, developmental disability; EKG, electrocardiogram; EPS, extrapyramidal symptoms; IM, intramuscular; IV, intravenous; MDD, major depressive disorder; mg, milligram; mg/kg, milligrams per kilogram; NGT, nasogastric tube; ODT, orally dissolving tablet; PO, by mouth.

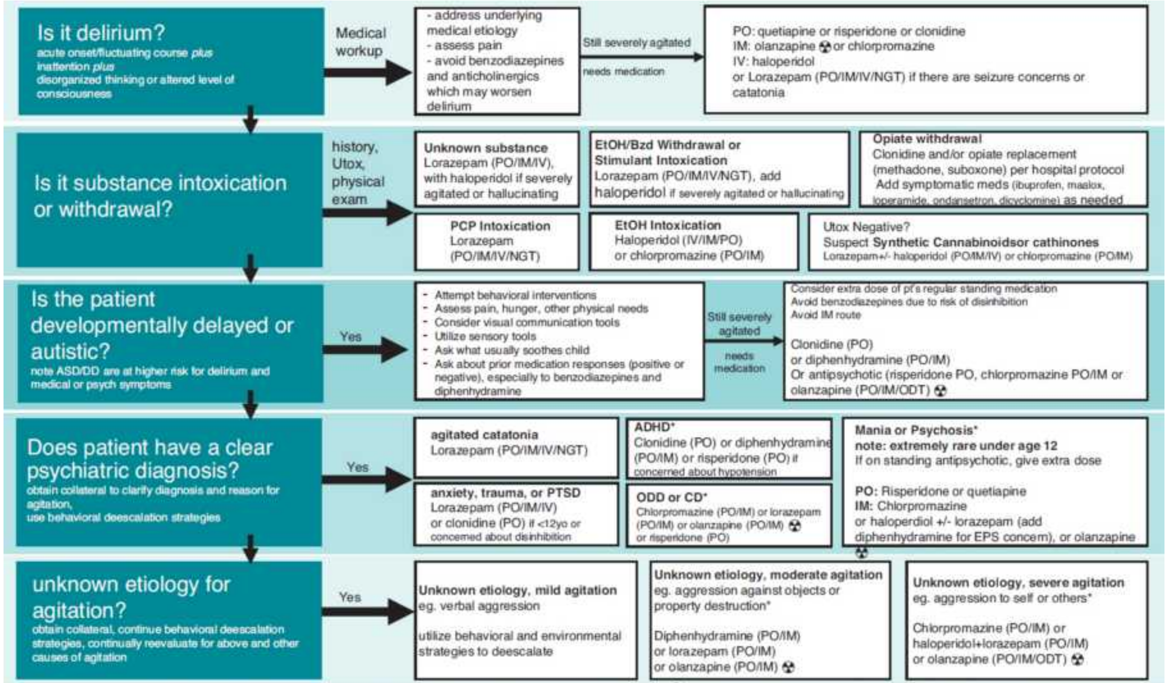
Best practices for evaluation and treatment of agitated children and adolescents (BETA) in the emergency department: consensus statement of the American Association for Emergency Psychiatry. *West J Emerg Med.* 2019;20(2):409–418. doi:10.5811/westjem.2019.1.41344. https://creativecommons.org/licenses/by/4.0/.

Choice of Medication in Treating Agitation

Agitation is a symptom, and treatment of symptoms requires a differential diagnosis for their etiology. Potential etiologic factors for agitation include physical pain or distress, anxiety, developmental disability, cognitive impairment, trauma, mania, psychosis, or difficulties with language and communicating needs. Evaluating for medical factors is critical, yet assessment may be limited by the child's agitated behavior; in such cases, clinicians should use their best clinical judgment based on the information available. Interventions should be targeted to the etiologic factors while considering a child's unique needs. Management of agitation specific to certain clinical conditions and situations is discussed below (Fig. 35.4–1).

Delirium. Delirium may stem from physical disease or medication factors and is characterized by an acute change and fluctuations in mental status with inattention, altered awareness, and cognitive deficits. The management of delirium should always seek to identify and address the underlying cause and should begin with nonpharmacologic interventions, such as treating pain or supporting sleep. Anticholinergics, benzodiazepines, and opioid analgesics may precipitate or exacerbate delirium, and thus the use of these agents should be minimized or avoided altogether. If additional medication is required, second-generation neuroleptics such as risperidone, olanzapine, and quetiapine are considered first-line agents. Haloperidol is considered a second-line agent, and if neuroleptics are to be avoided, clonidine may be used. The use of physical restraints should be avoided in medically compromised youth, and risk for falls and medical complications should be monitored in any delirium cases but particularly after psychotropic medication has been administered.

Substance Intoxication or Withdrawal. The approach to agitation in a youth who is intoxicated or in withdrawal should ideally be tailored to the specific substance at hand. However, when intoxication is suspected and the offending substance is unknown, lorazepam is generally preferred for the management of acute agitation. If the patient is suffering from severe agitation or hallucinations, lorazepam may be given together with haloperidol. However, neuroleptics should be used with caution, as they may exacerbate anticholinergic or sympathomimetic toxidromes. Finally, the use of medication is preferable to physical restraints in intoxicated patients, as physical restraints may lead to rhabdomyolysis, a sudden increase in serum potassium, and cardiac arrest.



Is it delirium?
acute onset/fluctuating course plus inattention plus disorganized thinking or altered level of consciousness
Medical workup
- address underlying medical etiology
- assess pain
- avoid benzodiazepines and anticholinergics which may worsen delirium
Still severely agitated
needs medication
PO: quetiapine or risperidone or clonidine
IM: olanzapine ☢ or chlorpromazine
IV: haloperidol
or Lorazepam (PO/IM/IV/NGT) if there are seizure concerns or catatonia
Is it substance intoxication or withdrawal?
history, Utox, physical exam
Unknown substance
Lorazepam (PO/IM/IV), with haloperidol if severely agitated or hallucinating
EtOH/Bzd Withdrawal or Stimulant Intoxication
Lorazepam (PO/IM/IV/NGT), add haloperidol if severely agitated or hallucinating
Opiate withdrawal
Clonidine and/or opiate replacement (methadone, suboxone) per hospital protocol
Add symptomatic meds (ibuprofen, maalox, loperamide, ondansetron, dicyclomine) as needed
PCP Intoxication
Lorazepam (PO/IM/IV/NGT)
EtOH Intoxication
Haloperidol (IV/IM/PO)
or chlorpromazine (PO/IM)
Utox Negative?
Suspect Synthetic Cannabinoidsor cathinones
Lorazepam+/- haloperidol (PO/IM/IV) or chlorpromazine (PO/IM)
Is the patient developmentally delayed or autistic?
note ASD/DD are at higher risk for delirium and medical or psych symptoms
Yes
- Attempt behavioral interventions
- Assess pain, hunger, other physical needs
- Consider visual communication tools
- Utilize sensory tools
- Ask what usually soothes child
- Ask about prior medication responses (positive or negative), especially to benzodiazepines and diphenhydramine
Still severely agitated
needs medication
Consider extra dose of pt's regular standing medication
Avoid benzodiazepines due to risk of disinhibition
Avoid IM route
Clonidine (PO)
or diphenhydramine (PO/IM)
Or antipsychotic (risperidone PO, chlorpromazine PO/IM or olanzapine (PO/IM/ODT) ☢
Does patient have a clear psychiatric diagnosis?
obtain collateral to clarify diagnosis and reason for agitation,
use behavioral deescalation strategies
Yes
agitated catatonia
Lorazepam (PO/IM/IV/NGT)
ADHD*
Clonidine (PO) or diphenhydramine (PO/IM) or risperidone (PO) if concerned about hypotension
Mania or Psychosis*
note: extremely rare under age 12
If on standing antipsychotic, give extra dose
PO: Risperidone or quetiapine
IM: Chlorpromazine
or haloperdiol +/- lorazepam (add diphenhydramine for EPS concern), or olanzapine ☢
anxiety, trauma, or PTSD
Lorazepam (PO/IM/IV)
or clonidine (PO) if <12yo or concerned about disinhibition
ODD or CD*
Chlorpromazine (PO/IM) or lorazepam (PO/IM) or olanzapine (PO/IM) ☢ or risperidone (PO)
unknown etiology for agitation?
obtain collateral, continue behavioral deescalation strategies, continually reevaluate for above and other causes of agitation
Yes
Unknown etiology, mild agitation
eg. verbal aggression
utilize behavioral and environmental strategies to deescalate
Unknown etiology, moderate agitation
eg. aggression against objects or property destruction*
Diphenhydramine (PO/IM)
or lorazepam (PO/IM)
or olanzapine (PO/IM) ☢
Unknown etiology, severe agitation
eg. aggression to self or others*
Chlorpromazine (PO/IM) or
haloperidol+lorazepam (PO/IM)
or olanzapine (PO/IM/ODT) ☢

*for these etiologies, in absence of consensus, medication options are listed alphabetically

☢ do not give olanzapine and benzodiazepines within 1h of each other

FIGURE 35.4–1. Agitation management clinical decision flow chart. (Reprinted from Gerson R, Malas N, Feuer V, et al. Best practices for evaluation and treatment of agitated children and adolescents (BETA) in the emergency department: consensus statement of the American Association for Emergency Psychiatry. *West J Emerg Med*. 2019;20(2):409–418. doi: 10.5811/westjem.2019.1.41344. https://creativecommons.org/licenses/by/4.0/.)

Autism Spectrum Disorder or Developmental Delays. Youth with autism spectrum disorder (ASD) or developmental delays may become agitated due to physical distress, sensory overstimulation, or mere changes in their routines. Such youth are also more vulnerable to adverse medication effects and may experience disinhibition or paradoxical agitation with benzodiazepines and diphenhydramine. Thus, behavioral strategies are especially important in addressing agitation in these youth. (Behavioral interventions for youth with ASD and ID are discussed in detail later in this chapter.) If medication is required for acute agitation, an additional dose of the child's regular standing medication is preferable to minimize the risk of adverse effects. Risperidone is a good option, as it is indicated for the treatment of aggressive behavior in ASD. If possible, IM medication and restraints should be avoided in youth with autism or developmental disabilities as such interventions can be highly distressing to these youth due to their sensory sensitivities.

Acute Psychiatric Illness. Youth may become agitated directly due to an underlying psychiatric illness, including anxiety, PTSD, or, more rarely, mania or psychosis. Youth with acute agitation due to anxiety or post-traumatic stress may benefit from diphenhydramine or a low dose of a benzodiazepine. Youth with agitation due to mania or psychosis will likely require haloperidol or another high-potency antipsychotic. However, it is important to remember that youth may become agitated for reasons that are little or completely unrelated to their psychiatric illness. They may be experiencing fear of anxiety, which could be relieved by alpha-2 agonists, diphenhydramine, or benzodiazepines.

Diphenhydramine and lorazepam are often utilized in cases of moderate agitation where the etiology of the agitation is not clear. For severe agitation of unknown etiology, olanzapine, chlorpromazine, or lorazepam combined with haloperidol may be used. These neuroleptics carry more significant risks, including extrapyramidal symptoms (EPS), neuroleptic malignant syndrome, and adverse cardiac effects, such as QT prolongation. Total daily doses should be closely monitored, and “do not exceed” instructions should be clearly written. If there exists significant concern for QT prolongation or other dysrhythmias, cardiac monitoring should be considered. Youth who are antipsychotic naive and are given high-potency neuroleptics for agitation are at increased risk for EPS. Diphenhydramine or benztropine may be utilized as prophylaxis for EPS and acute dystonic reactions, and adding these agents to haloperidol (Haldol) can magnify the sedating effect of the antipsychotic. Olanzapine is more sedating and carries a lower risk of EPS and adverse cardiac effects than other neuroleptics. However, olanzapine carries a higher risk of respiratory suppression if parenterally administered within 1 hour of benzodiazepines, and thus such concomitant administration should be avoided.

Assessment of Developmental Factors in Psychiatric Emergencies

Children are not just little adults, physically or psychiatrically. When faced with a child in crisis, the interpretation and significance of the child’s symptoms will vary greatly depending on the developmental status of the child. The developmental status includes not only the child’s chronologic or physical age but also any developmental delays, cognitive disabilities, genetic or metabolic syndromes, or deficits in speech, language, or learning ability. The ED clinician may not have access to a complete developmental history of the child, but observation of physical signs of genetic or developmental syndromes and of cognitive and motor skills can flag whether a developmental or cognitive delay may be present.

Acute symptoms can have different causes or meaning in children of different age and developmental stage. For example, a young child may present to the ED with “hallucinations” that are age-appropriate imaginary friends. An adolescent with significant ID may have a similar presentation, which would be concerning in a child of that age without ID but may still be normative in the presence of the disability. Sexual behaviors are another important example. Many children are brought to the ED for “sexual acting out.” A 5-year-old child who exposes his genitals to a peer and asks the peer to do the same is engaging in normal, common behavior for a child of that age. A similarly aged child who touches a peer’s or adult’s genitals is still within the normal range of behaviors for that age, though the behavior may reflect poor impulse control or emotional immaturity. If a 14-year-old boy is sent to the ED from school after touching a peer’s genitals without invitation to do so, this could be a predatory behavior, but it is important to assess whether a developmental or cognitive delay is present, as a 14 year old with autism or ID may be closer to the 5 year old’s developmental maturity than his 14-year-old body would suggest. Children with autism and ADHD are particularly likely to have disparities between their physical/cognitive age and their emotional/developmental maturity. Often children present to the ED with concerning behaviors or symptoms that look like psychosis or other acute illness, but a careful developmental history identifies undiagnosed autism or other developmental delay.

Assessment of Contextual Family and Social Factors Contributing to Psychiatric Emergencies

Children and adolescents present to the ED with a range of acute psychiatric complaints, from recent-onset psychosis or mania to longstanding obsessive-compulsive disorder (OCD) or autism. An important question for any child in the ED is why now—what has led the child to be brought today and not yesterday or tomorrow, and what were the precipitating factors that contributed to this? Even when a child presents with an acute or new-onset illness such as psychosis or mania, it did not begin just minutes before their arrival to the ED; rather, someone became aware of the child’s symptoms, or something happened that was the tipping point for the child or family to seek help. Understanding these contextual factors is important to stabilize the crisis. For example, an adolescent may have been abusing opiates for weeks, but today stole money from his mother and became violent toward her. Stabilizing this crisis will require treatment for the child, but also support for his mother if she is to effectively care for him going forward. A young child sent from school for a tantrum may have longstanding ADHD, but the immediate triggers for his tantrum were frustration with schoolwork related to having been transitioned this week from a special education classroom to a mainstream one. His treatment may involve changes in his ADHD medications, but also increased academic supports. A teenage girl with autism is sent to the ED for head-banging and other self-injurious behaviors, but her symptoms are related not only to her autism but also to her caregiver's recent surgery that led to the girl staying with her aunt for 3 days. A safe discharge for her will be more dependent on psychoeducation and support for her aunt than on additional medication for behavioral control.

The key contextual factors to assess are the child's home and family context; educational setting; and social factors. In the home and family sphere, the child's symptoms may be acutely worsened by shifts in the physical environment (e.g., moving into a different apartment or shelter), changes in the family makeup (birth of sibling, remarriage, divorce or death, or a move into foster care), or conflict or violence in the home. These factors may directly impact the child's mental health or may decrease the parent's ability to cope with symptoms, provide structure or supervision, or manage difficult behaviors. A parent may also be suffering from mental illness or substance abuse, or may be abusive, neglectful, or failing to protect the child from abuse or maltreatment. Understanding the child's home and family context can also highlight key strengths and supports for the child that may be useful in treatment and safety planning.

Multiple factors in a child's educational setting can precipitate an ED visit. Many children presenting to the ED are sent from school, often with a mandate for "psychiatric clearance" before the child will be allowed to return. When a child is sent from school, it is important to understand both the general academic context and learning needs of the child, to assess for unmet needs or mismatch, and the immediate triggers for the child being sent to the ED. For example, for the child with ADHD who has a tantrum after being transitioned from special education to mainstream classes, it will be useful to know as well that the tantrum occurred in math, his worst subject, after he was being teased by peers for being a “retard.” This child will have a different treatment plan than a similar boy with ADHD who has a meltdown during a fire drill, when his family recently became homeless after a fire destroyed their apartment building. Each of these boys can be discharged home but are likely to return to the ED with a similar outburst within days or weeks if the contextual factors are not addressed.

Social factors are also important to assess, particularly for adolescents. A child’s social milieu can be a crucial support in a crisis, or a trigger for acute pathology. Self-injurious behavior, substance use, risky sexual behaviors, and suicidality can have strong peer effects among adolescents and preteens. Conflicts within friendships, romantic breakups, bullying, and cyberbullying can precipitate suicidal thoughts and serious violence. Relationship violence and date rape is also unfortunately common among adolescents. Social isolation can be a marker for serious psychiatric illness, be it chronic (in the case of autistic or otherwise “odd” youth) or acute (for depressed, prodromal, or psychotic adolescents).

SPECIFIC PSYCHIATRIC EMERGENCIES IN CHILDREN AND ADOLESCENTS

Suicidality and Self-Harm

Assessment. As noted above, suicide is a leading cause of death in adolescents, and is one of the most common psychiatric presentations of youth to the ED. When a child or adolescent presents to the ED after a suicide attempt, medical stabilization is the foremost step. After this, the ED clinician must determine the patient’s suicide risk and whether inpatient hospitalization (including potentially 1:1 observation for safety) is required. Guidelines vary but generally recommend universal screening of youth presenting with psychiatric concerns, structured risk assessment, safety planning, discussion of means restriction, and referral for treatment.

Suicide screening has been shown to be effective in detecting suicide risk, as well as feasible and acceptable to patients and families. Examples of brief, evidence-based, standardized suicide screening tools for children and adolescents include the Ask Suicide-Screening Questions (ASQ), which consists of four self-report questions, takes 20 seconds to administer, and was developed for use in EDs. Another example is the Tri-Factor Screen for Youth, which consists of 22 self-report questions and takes 3 to 4 minutes to administer. The SAFE-T prompts clinicians to inquire about suicide risk and protective factors and suicidal thoughts, and based on these, suggests a risk level and possible interventions. The Columbia-Suicide Severity Rating Scale (C-SSRS) includes questions on various aspects of suicidal ideation (such as intensity and frequency), preparatory behaviors, and past suicide attempts (including aborted/interrupted attempts, and the lethality and medical consequences of attempts). The C-SSRS has been studied in adolescents with psychiatric emergencies and a pediatric version is available. While depression screening tools, such as the Patient Health Questionnaire-9 (PHQ-9) have been used to identify youth at risk for suicide, these can miss nondepressed youth with suicidal thoughts.

When a youth screens positive for suicide, clinicians should perform further assessment to ascertain the level of suicide risk and determine the level of care needed. A careful assessment of suicidal thinking and behavior is crucial. The ED clinician should ask about the ideation and planning leading up to the attempt, including the anticipated lethality of the attempt, if the child thought someone would discover or rescue them, if a suicide note or other preparation for death was made, and if the child experienced regret or ambivalence after the attempt and immediately called for help, or took steps to ensure no one would find out or be able to help them. The clinician should also assess current active or passive suicidal thoughts, plans, intent, future orientation, and reasons for living, though with recognition that youth may be motivated to minimize their current suicidal thoughts or intent for fear of being hospitalized or upsetting family members. The mental status examination can identify mental states that confer acute risk for suicide, which may be more difficult for a child to minimize or hide; these include hopelessness, preoccupation with death, severe depression, command hallucinations, and feelings of worthlessness. Other risk factors include prior suicide attempts or ideation; substance use; prior psychiatric diagnosis (depression, bipolar disorder, substance use, and conduct disorders confer particular suicide risk); family history of suicide; and access to firearms and other means of self-harm.

It may not be immediately obvious when a child in the ED has made a suicide attempt. Hanging attempts and self-poisonings may have clear suicidal intent, but other youth may present with self-cutting, overdoses of prescription drugs, threats to stab self or jump from high places, attempts to drown in the bathtub, or other acts where the true suicidal intent is unclear. It is important not to dismiss “dramatic” suicidal gestures as related to personality disorder as might be done in adult patients, as in children and adolescents even suicidal gestures and parasuicidal behaviors often demonstrate real risk. If the child engaged in deliberately harmful behavior that could be reasonably expected to end their life with the intent to end their life, the term “suicide attempt” should be used. Moreover, behaviors of unclear suicidal intent can still indicate a very real risk for suicide. Even if the child is repeatedly self-cutting with no current suicidal intent, the fact of engaging in repeated self-injury is a risk factor for later suicide attempts, and even youth who engage in suicidal behavior with ambivalence or for attention can inadvertently hurt themselves (e.g., youth who take overdoses of acetaminophen without realizing its potential lethality). In addition, children might misjudge the dangerousness of their behavior, which therefore may not accurately reflect the severity of their suicidality. A child presenting after a behavior of seemingly “low lethality,” such as an “overdose” using a small number of over-the-counter pills may nevertheless have intended to end their life.

While the determination of a suicide risk level rests on professional clinical judgment, it is important to note that assessing suicide risk or determining a risk level is not the same as “predicting suicide.” Clinicians cannot predict suicide; they can only attempt to assess imminence and severity of risk with the goal of instituting appropriate treatment. There are also no definitive guidelines on weighing suicide risk factors, distinguishing between “chronic” and “imminent” risk, or reassessing risk levels over time. Clinical judgment is imperfect, and while underestimating risk is of concern, a “high-risk” label may also carry unnecessary restrictions that are costly, aversive, and possibly even detrimental, such as separating youth from their families, peers, and communities through hospitalization. It is important to remember that while many youth have risk factors for suicide, few actually complete suicide, and that while suicide risk can be mitigated and reduced, it cannot be completely eliminated.

Management. The first decision in managing a suicidal patient is determining the need for inpatient hospitalization. Inpatient admission may be needed for the following:

- Serious suicide attempt, with or without endorsing persistent or current suicidal thoughts
- Persistent, intense suicidal thoughts or intention
- Suicidal ideation/behavior in the context of severe depression, command auditory hallucinations to self-harm, hopelessness, or self-blame
- Suicidal ideation/behavior in the context of a profound psychosocial stressor, such as recent sexual trauma or disclosure of abuse, severe bullying, relationship loss
- Suicidal ideation/behavior in the context of poor supports (family rejection/stress, no outpatient treatment)

If the clinician is uncertain whether a child is safe for discharge, it is most prudent to hold the child for reassessment of suicidal ideation and for additional collateral history. Discharge with outpatient treatment may be appropriate for youth with a low likelihood of acting on suicidal thinking and no intent or plan to do so, and who have a responsive and supportive family or other caregivers who can intervene if their suicidal thinking or other symptoms worsen.

Before discharge, youth and families should be engaged in safety planning, discussion of means restriction, and commitment to ongoing treatment. These brief interventions have been shown to significantly decrease suicide attempts in the months following an ED visit and can improve continuity of care. Several structured interventions have been developed, and they generally focus on promoting safety, providing follow-up care, and enhancing connection with trusted adults.

Safety planning is a key intervention for children and adolescents presenting to the ED with suicidality, even those not at high risk. Creation of a safety plan involves helping the child identify triggers for suicidal feelings, coping strategies that the child can use if suicidal thoughts present, whom the child can call on for support and what those individuals should do to help the child, and how to access professional help or return to the ED if needed. For youth who struggle to identify triggers, a review of the “chain of events” that led to the current presentation is helpful. The safety plan should include 24/7 crisis hotlines or text lines and should be shared with the parent or guardian. Safety plans can also be useful for self-injurious behavior without suicidal intent by modifying the plan to focus on urges to self-harm rather than on suicidal thoughts. It is also helpful to explore the function of the self-harm, which may include internal reinforcement, such as relief of strong negative emotions or feelings of numbness, or external reinforcement, such as attention from peers or family or release from social situations or conflicts with which the child is otherwise unable to cope. The ED clinician should view self-injurious behavior not as manipulative but as representing an inability to cope or communicate distress and thus demonstrating the need for treatment.

Caregiver engagement is key for safe discharge. The safety plan should be shared with the parent/guardian, and they should be educated on the importance of restricting access to lethal means (and to drugs or alcohol that increase risk for suicidal behavior), increasing supervision, and improving listening and opportunities for positive connection with the youth.

Ensuring access to follow-up care is also critical. The child should be set up with prompt (within a week) outpatient follow-up for reassessment of suicide risk and to work to stabilize the psychological and social factors that led to the suicidal thoughts and behavior. Treatments such as dialectical behavior therapy (DBT) have shown promise and appear to be effective in reducing suicide attempts and self-harm among youth. Unfortunately, these specialized therapies may not be accessible to many youths at risk for suicide; this underscores the importance of the care, counseling, and intervention provided at the ED visit.

Of note, “no suicide” or “no harm” contracts are not recommended. They have not been shown to be effective, may discourage patients from seeking help should suicidal thoughts return, and may give adults a false sense of safety.

Aggression

Assessment. Youth can present to the ED with aggressive behaviors ranging from overblown tantrums to planned, intentional, and even lethal violence. The assessment of such youth starts with managing the child’s behavior in the ED, using the techniques described above to de-escalate and contain the youth’s behavior with verbal interventions, medication, and restraint or seclusion when indicated. The child’s response to these interventions will be telling for both diagnosis and risk assessment. An adolescent who is unable to respond to verbal de-escalation and seems to be disorganized or paranoid may be psychotic or intoxicated. A child who is brought by police or school safety officers cursing and kicking but is able to speak calmly to the clinician once the uniformed officers have left may be, by contrast, an impulsive child with ADHD or PTSD who became agitated due to teasing at school but with no true intent to harm anyone.

Once the initial agitation is addressed, the clinician must attempt to understand the aggressive behavior. Understanding from the child's perspective the triggers for their aggression can make a frightening experience into a therapeutic opportunity. The clinician should assume that there is always a reason for the aggressive behavior, even if the child cannot immediately articulate it. The reason may not be obvious to the clinician or even to the child at first, but empathic and patient questioning (and information from collateral sources) can uncover the triggers, both external (such as teasing or other provocative behavior from peers, being told "no," a disruption of routine, being touched by staff or police) or internal (frustration, anxiety, paranoia, command hallucinations, trauma flashbacks). The clinician should also attempt to ascertain the context of the aggressive behavior, including evidence of planned or premeditated aggression, homicidal intent, weapons involvement, or a history of severe or escalating violence.

Aggressive acts can be reactive (in response to a trigger or perceived insult) or instrumental (planned with intent to harm or to use aggression to get something). Reactive aggression is unplanned, unprofitable, and poorly controlled. Reactive aggression may be triggered by events that appear benign to adults, like a school staff putting a hand on the child's shoulder to calm them, but which feel intrusive or threatening to the child due to their background and history. Children with autism, ID, and learning disabilities may become aggressive when frustrated because they lack the verbal skills to solve the problem and express themselves, or because they do not know any other way to ask for what they want. On the other hand, instrumental aggression is planned, profitable, and self-controlled. It often represents a reaction to narcissistic injury or stems from a belief that aggressive behavior is an appropriate means to gain desired end or exert power.

Management. Once the initial agitation is addressed, the clinician's job is to determine whether the child can be safely discharged. Risk for future violence depends in part on the nature of the violence, and on the presence or absence of underlying psychiatric illness. Evidence of planned or premeditated aggression, homicidal intent, weapons involvement, or a history of severe or escalating violence, all confer an increased risk. Risk may be influenced by parental disciplinary practices, child-rearing style, and history of substance use or criminality. Risk may also be elevated by social factors such as association with gangs or delinquent peers.

Management must be tailored based on the nature of the aggressive behavior, whether it stems from an underlying psychiatric illness, and the level of risk. Youth with a range of psychiatric illness can be prone to reactive aggression, and the treatment for each must be targeted to the illness or symptoms present (Table 35.4–4). Instrumental aggression is less common in mentally ill youth, but can be seen in conduct disorder and substance use.

Psychosocial interventions and behavioral strategies are central and should be considered first-line treatment. When aggression is reactive, the treatment involves identifying triggers, teaching skills to cope with those triggers without aggression, and addressing the core symptoms that predispose the youth to aggressive behaviors. Children with impulsive aggression benefit from parent–child skills training programs and the effective parental use of verbal warnings, prompting, “time outs,” and other behavioral interventions. Treatment of underlying conditions (such as ADHD, autism, or PTSD) is also important.

Table 35.4–4.
Examples of Psychiatric Illnesses in Children That Can Lead to Aggression

Illness/Symptom	Treatment Focus
ADHD	Address impulsivity
ODD	Set clear limits, reinforce positive behaviors
Psychosis	Treat command hallucinations/paranoia that are triggering aggression
Mania	Stabilize mania to address impulsivity/irritability
Autism or intellectual disability	Promote verbal problem solving and other coping behaviors
Conduct disorder	Set clear consequences for antisocial behaviors and reinforce positive behaviors
Substance use	Increased supervision, motivation enhancement techniques to reduce use

ADHD, attention deficit hyperactivity disorder; ODD, oppositional defiant disorder.

When aggression is instrumental, treatment involves setting clear consequences, often in collaboration with parents and law enforcement, while promoting prosocial behavior with positive reinforcements. Youth with instrumental aggression often benefit from interventions such as multisystemic therapy (MST), which addresses family relationships, parent–child communication, parenting skills, school involvement, and peer activities.

If medication is necessary, it should comprise only one aspect of a comprehensive treatment approach and should be used to address the core conditions and symptoms that predispose the youth to aggressive behaviors. While the use of emergency medication may at times be required (as discussed above), the use of PRN medication is not considered standard outpatient treatment for aggression in youth, and should be avoided. If severe aggressive behavior persists despite adequate medication trials to target the underlying psychiatric condition, antipsychotic and/or mood-stabilizing medication may be considered.

Determining whether inpatient hospitalization is indicated depends both on immediacy of risk for further aggression, and on whether the risk for aggression is due to mental illness and will be helped by hospitalization. There are youths who are engaging in criminal behavior not due to psychiatric illness, and for them, inpatient hospitalization may not be helpful; in such cases, clinicians should collaborate with the parents and law enforcement to identify other supports to contain the youth's behavior. If the child's aggression stems from abuse at home or if the family cannot safely supervise the youth, a referral to child protective services may be necessary.

If the aggressive behavior is rooted in psychiatric illness yet there is no imminent risk of harm or significant change in the youth's mental status and the youth's family can contain the behavior, the youth may be safely discharged with outpatient treatment. Prior to discharge, clinicians should engage the youth in creating a safety plan. Similar to safety plans for suicidality (see above), safety plans for aggression should identify triggers and warning signs for aggressive behaviors, coping skills to safely manage situations that may lead to aggression, and supports. Clinicians should also help families establish a crisis or emergency plan and provide 24-hour crisis hotlines in case the youth's aggressive behavior worsens. Active family engagement is critical to the successful management of youth aggressive behavior. Families of aggressive children may by struggling with stigma or feelings of overwhelm, guilt, and shame. Moreover, their child's behavior may have compromised their ability to obtain community support. Providing referrals for support groups, parent advocates, and educational resources will enhance the family's support and facilitate their ability to engage in their child's treatment.

Risky Behaviors and Substance Use

Assessment. Drug use, running away, truancy, risky sexual behaviors including prostitution, gang involvement, and other dangerous behaviors can prompt parents to bring a child to the ED desperate and looking for help. Such behaviors are uncommon in youth and can have serious and even fatal consequences; yet often the child is not immediately "dangerous to self or others." The ED clinician must assess whether the child's behaviors are age-appropriate limit testing, a reflection of underlying psychopathology, or a response to problems in the home or failures of supervision, and whether the risk of the behaviors is sufficient that hospitalization is indicated.

Determining safety is, as always, primary; this may involve assessing whether the youth is currently intoxicated with substances or at risk for withdrawal or whether a rape kit or sexually transmitted disease (STD) testing and prophylaxis are indicated. Some risky behaviors are isolated incidents that the youth will learn from and not repeat. Youth in the ED for such behaviors will usually claim that this is the case, so collateral information is crucial to assess for repeat behaviors, a decline in functioning, or associated psychiatric symptoms. Risky behaviors can be related to a range of psychiatric illnesses, including depression, mania, PTSD, ADHD, and conduct disorder, and can also be seen in intellectually disabled or autistic youth who may not comprehend the dangerousness of their actions. They can also reflect problems in the child's environment, such as a parent's inability to provide sufficient supervision due to illness or work schedule, or the child's reaction to a divorce or other major stressor in the family. In cases of truancy, the behavior may be a response to bullying, insufficient academic supports, or an inappropriate classroom placement for a child with special learning needs. Approaching the patient with an empathic and nonjudgmental stance is key to understanding why they are engaging in these behaviors and assessing their motivation to change.

Management. When risky behaviors put the child at immediate risk for harm, or when they are secondary to underlying psychopathology or problems in the environment, further intervention is needed. For a manic youth having promiscuous unprotected sex and abusing drugs, though this youth may not be suicidal or homicidal, they are endangering themselves and others and will continue to do so until their mania is treated. For an adolescent with ID who is running away and associating with gang members because his mother is medically ill and unable to supervise him, coordination with child protective services and law enforcement may be required to provide more support or place the child in a residential facility with greater supervision. Bolstering the parent's ability to relate to and engage the child will help them to prevent risky behaviors in the future. Often, the parent is so upset, angry, or anxious about the child's behavior that they are unable to effectively relate to the child, and the ED clinician must help the parent to contain their affect and set reasonable expectations. If the child and parent are unable to agree upon basic rules and behavioral expectations, then outpatient treatment has little chance for success and the ED clinician should coordinate with social work, case management, child protective services, and any services currently involved with the child to bolster the family's capacity to keep the child safe.

Psychosis

Assessment. Children and adolescents are often sent to the ED from school or from outpatient providers due to concern for psychosis, particularly for command hallucinations to harm self or others. Yet, chronic psychotic disorders like schizophrenia are extremely rare in children, instead usually developing insidiously in the late adolescent or young adult years. The ED clinician will often be in the position of discerning whether a child who is sent for "hearing voices" or being "internally preoccupied" is a child with early-onset schizophrenia, in need of inpatient hospitalization, or, more likely, that this is a red herring. Young children can report "hearing voices" as a way to express their own thoughts (particularly thoughts that are shameful, uncomfortable, or that might get them in trouble), and older children and adolescents with ID or autism often do the same. Imaginary friends are also normal in children, and again, adolescents with ID whose cognitive age is much lower than their chronologic age may endorse imaginary friends much longer than their neurotypical peers. Children with autism and ID are also often sent to the ED for being "internally preoccupied" or "responding to internal stimuli," but this may be a symptom of their autism, not of psychosis. Often these children have never been diagnosed with autism or ID if the family has not been consistent with medical providers or closely involved with the child's school. Children who have suffered a loss can report hearing or seeing their loved one in the context of grief. Anxiety disorders and OCD can present with thinking that borders on delusional, and post-traumatic flashbacks can look like the child is experiencing hallucinations. Depression and mania can be accompanied by either nihilistic and shameful or grandiose delusions and, at times, hallucinations berating or shaming the patient. An accurate diagnostic assessment is crucial as the treatment will vary greatly depending on the diagnosis and clinical formulation. Collateral information about the child's life, family, functioning, recent stressors, and prior traumas is important, particularly if the child is disorganized or cognitively limited and unable to give coherent answers.

If the clinician determines that the child is truly psychotic, organic causes must be ruled out. A complete physical examination, lab analysis including complete blood count, electrolytes, liver, kidney, and thyroid functioning, full toxicology screening, and brain imaging are indicated, as well as other tests (Lyme, erythrocyte sedimentation rate, rapid plasma reagin, lumbar puncture for cerebrospinal fluid analysis, etc.), depending on the patient's history and associated symptoms.

Management. Patients who are truly psychotic can be dangerous in the ED as they may act erratically and expose themselves or others to danger. These patients often require a 1:1 sitter for observation and close monitoring. Youth with psychosis can rarely be stabilized in a few hours in the ED and generally require inpatient hospitalization for stabilization. If the psychosis is secondary to substance intoxication, the symptoms may clear when the intoxication subsides, but with the new designer drugs such as synthetic cannabinoids (k2, spice) and substituted cathinones (bath salts), substance-induced psychosis is of much longer duration than with more traditional drugs and may require inpatient hospitalization for safety. If the psychotic symptoms are due to severe depression, mania, or OCD, or if the ED clinician lacks the collateral information and time to observe the patient to make a definitive diagnosis, hospitalization may be the best option to keep the child safe and treat the child carefully.

If the reported psychotic symptoms are in fact a manifestation of ID or immaturity, anxiety, grief, trauma, or a normal reaction to stress, the child can likely be discharged with a referral for outpatient treatment and reassurances for the child and family. Families in these cases are often deeply relieved and should be reminded that even though their child is not being diagnosed with schizophrenia, follow-up psychiatric care is still important. Depending on the underlying psychopathology, the ED clinician may also consider starting treatment from the ED (e.g., medication for anxiety or psychoeducation about trauma and flashbacks).

Youth with Autism and Intellectual Disability

Assessment. Children and adolescents with ASD and/or ID, particularly those with limited or minimal verbal communication skills, are often brought to the ED for behavioral symptoms, including aggression, self-injury, inappropriate sexual behaviors, sleep cycle reversal, or running away. These cases can be difficult for the ED clinician because youth with ASD or ID can be medically and psychiatrically complicated, and also they often have a difficult time in the ED due to the unpredictability and unfamiliarity of the ED, the noise, bright lights, and the need for blood draws and physical examinations. Children with ASD or ID often are blocked from admission to inpatient psychiatric units due to their diagnosis, leaving them boarding in the ED for days awaiting an inpatient bed on a specialized unit.

When youth with ASD or ID present to the ED, the first step to keep them safe is to understand what works at home, including preferred toys and caregivers, communication tools (such as picture communication tools and sign language), and soothing techniques. Understanding what typically triggers negative behaviors at home will also help the ED clinician to avoid outbursts in the ED. When a child with ASD or ID is brought to the ED for problematic behaviors, it is important first to understand if the behavior is longstanding or new. Longstanding behaviors such as self-stimulatory behaviors, impulsive aggression, or head banging may be related to the underlying ASD/ID and indicate that the community treatments are insufficient or ineffective and should be re-evaluated. New behaviors are often triggered by changes in the environment (changes in caregiver or home environment, school vacation, changes in school placement) or physical/medical problems (constipation, dental problems, ear infections, seasonal allergies, pain, fatigue, sedation due to polypharmacy, adverse effects from medication such as akathisia, onset of puberty). More rarely, the youth with ASD/ID can have the new onset of a psychiatric disorder such as a mood or anxiety disorder, but environmental changes and medical problems should be ruled out before a new diagnosis is made.

Management. Keeping patients with ASD and ID safe in the ED requires the removal of unnecessary stimuli (noise, light, needle sticks), clear communication (simple, concrete, and written or picture based if possible) of what to expect from the evaluation, attention to physical comfort (pain, fatigue, hunger, constipation), and use of soothing activities or family members when possible. Oftentimes, the parents of ASD and ID youth are the “experts” in knowing which strategies calm and help their child. Family members may also serve as “interpreters,” helping ED staff understand the significance of their child’s actions and behaviors. Involving child life specialists, occupational therapists, speech–language therapists, and other health professionals may help tailor ED care to the youth’s needs. Medication is often used to sedate ASD and ID patients in the ED. However, this is dangerous as they may have paradoxical reactions to medications such as diphenhydramine and benzodiazepines yet have little positive effect from antipsychotics. Behavioral interventions, while more complicated to execute, are much more likely to be effective.

Many youths with ASD/ID can be stabilized quickly if the medical or physical etiology of their distress is discovered and resolved. Effective pain control, dental care, management of insomnia and constipation, and resolution of polypharmacy and medication adverse effects can be accomplished in the ED and provide great relief to patients and families. Often when these problems are resolved, families discover that their child, who had been increasingly aggressive or difficult to manage for a long time, is now calm and comfortable.

As there are few inpatient units that accept youth with ASD or ID (particularly if they are aggressive or engage in self-injurious behaviors), ED clinicians should familiarize themselves with community services available for people with intellectual and developmental disabilities. Often home-based and respite services are available to patients who qualify, though families may not know how to access these services.

Child Abuse or Neglect

Assessment. Unfortunately, it is all too common that youth who present to the ED for psychiatric complaints are found to be the victims of child abuse or neglect. Children with psychiatric and developmental disorders and behavioral disturbances are more likely to be abused and neglected, and abuse and neglect can contribute to the development of a range of psychiatric illnesses. Other risk factors include poverty, single-parent households, large family size, social isolation, parental substance use, and personal history of abuse for the parent. Assessing for abuse or maltreatment in the ED is very difficult, because children rarely admit to abuse, due to shame, guilt about betraying the family if the abuser is a family member, or fear of reprisal or removal from home. Clear evidence of abuse is rare. Children can present with medical symptoms such as unexplained physical injuries, signs or symptoms of sexually transmitted diseases, or blood in their underwear, and then the psychiatric clinician consults the pediatric team for further evaluation for abuse. Children who are being abused or maltreated can also present to the ED with a wide range of psychiatric symptoms.

The ED clinician must ask in a careful, thorough, nonjudgmental way about any abuse or maltreatment in the home, school, or elsewhere. The child should be interviewed separately from the parent and should be reassured that he will be safe and protected no matter what he discloses. It is important to interview the child gently, starting with more subtle queries into the child's home life (such as who lives in the home, who prepares meals, who helps with homework) and then moving to questions about who sleeps in bed with whom, who gets into arguments and how they are resolved, who yells the most at home, what punishments there are for misbehavior, and other contextual questions before asking directly about abuse. Collaboration with the pediatrician, if any physical injuries are present, can also be helpful as these may be a marker for abuse, or the child may require a genital examination if there is a concern for sexual abuse. When child abuse pediatrician consultation services are available, it can be helpful to obtain a specialized interview and physical examination to discover and document evidence of abuse. At the very least, when abuse is suspected, child protective services should be consulted immediately. It is not the ED clinician's job to determine whether abuse has definitely occurred (that is the job of child protective services). But if there is any concern, as a mandated reporter, the ED clinician is obligated to call child protection. Parents should be notified that such a call is being made and why; even if the parent is the perpetrator or failed to prevent abuse, they are often remorseful and looking for help if the clinician is able to empathize with why the abuse has happened (such as a battered mother unable to prevent the abuse of her children, or an overwhelmed parent struggling to discipline a child with significant behavioral problems). The parent may need help as much as the child does, so maintaining an empathic alliance with the parent will give them and the child the best chance for recovery.

Medical child abuse can manifest with exaggeration or fabrication of a child's psychiatric symptoms. This is very rare and difficult to diagnose but can manifest in the ED with hospital shopping, strange recurrences of symptoms despite good treatment, requests for specific medications, tests, or procedures, and refusal to consent for the ED clinician to contact outpatient providers or other key collateral sources. The ED clinician should be cognizant that medical child abuse can present with psychiatric symptoms and should utilize tools for collateral information such as state prescription databases, pharmacy, and insurance records if such an etiology is suspected.

Management. Collaboration with child protective services will help to ensure the child's immediate physical safety, and this may require keeping the child in the hospital until an investigation is done and a safe place is found to which the child can go. The ED clinician can also play an important role in assessing for psychiatric sequelae of maltreatment, providing psychoeducation to the child and family (or foster family), and ensuring that the child receives appropriate psychiatric follow-up care. If the child presents to the ED with behavioral problems, helping the family or caregiver to identify how these behaviors may be triggered by or related to the trauma or abuse can help avoid such behaviors (and repeat trips to the ED) in the future. Family therapy can be a very helpful referral in these cases. Anticipatory guidance can also be helpful for both the child and caregiver to understand what types of symptoms may come up in the future and how to access help if needed. If a child is to be discharged, clinicians should consider the child's environment and circumstances after leaving the ED. Whether the child will be discharged to the custody of child protective services, a foster home, a group home, a residential facility, or returning home with their caregivers will impact their needs for treatment referrals and aftercare. If a child is in a chaotic or unpredictable situation, this should prompt reconsideration of any medications that require frequent monitoring and increased attention to ensure access to follow-up care.

Eating Disorders

Assessment. Eating disorders are a source of significant morbidity and mortality in children and adolescents. When an eating disorder is discovered by a parent or teacher, the adult will often send the child to the ED for medical and psychiatric evaluation due to concern for the medical consequences of eating disorders as well as their association with suicidality and self-harm. The ED clinician may also discover an undiagnosed and unrecognized eating disorder in a child or adolescent who presents to the ED with dizziness, nausea, syncope, suicidal ideation, or self-injury. Younger children and boys may present to the ED with unexplained weight loss, and often no one has asked them about restricting, purging, or excessive exercise because clinicians are unused to seeing eating disorders in prepubertal patients or in males.

Management. Children and adolescents with eating disorders may require psychiatric hospitalization for safety due to suicidality or self-harm, or they may require medical admission for medical stabilization. Collaboration with pediatrics is crucial in all cases to determine the treatment plan and need for hospitalization. Assisting the family to identify resources for support and education is also important, as an effective treatment of eating disorders is a long-term process that requires close family involvement for the greatest success.

Psychosocial Crisis

Assessment. Children are profoundly affected by a parent’s state of mind, mental health, and relationships. Parental mental illness, divorce, or severe conflict between parents can manifest in emotional and behavioral problems in the child. These stressors put the child in a desperate situation, and for a child with underlying psychiatric or behavioral symptoms, these family crises can be catastrophic. These situations can be difficult to assess. The parent is often unable to objectively reflect the stress on the child or even on the parent’s own internal life and struggles. The child may lack the emotional maturity to describe clearly the problems at home, feel guilty, ashamed, protective of the parent, or be afraid of being separated from the family. “Listening between the lines” is important, and when the given history does not make sense, it can be an indication that hidden stressors at home may be at the root of the child’s presenting problem. The child and parents should each be interviewed separately, and the clinician should approach the parent empathically and make it clear that their purpose is to help the child, not to be intrusive, judge the parents, or report them. If parents give deeply discrepant reports or perspectives on the child’s symptoms, blame the other parent or the child, or belittle or berate the other parent or child, this suggests a significant conflict in the family that may be triggering the child’s symptoms or behaviors or making it impossible for the family to effectively manage those symptoms or behaviors. When speaking with the child, vague or inconsistent statements that seem odd or unusual to the interviewer (such as a child who states that the parent is sleeping most of the day and cannot be awoken) may serve as “red flags” and reassurance and specific questioning to the child may help them share the problems at home.

Management. Safety is, as always, the first priority; if a parent is severely mentally ill or if the conflict in the home is so extreme, then child protective services should be notified. The ED clinician may, in extreme cases, also need to refer the parent for their own emergency assessment. In less severe cases, with an empathic and strong rapport with the parents, the ED clinician may be able to help the parent to understand their role in the child’s symptoms and their need for help and treatment. Getting the parent into individual or family treatment and helping the child to voice and cope with the stress at home will reduce the child’s distress and the strain on the family.

LEGAL CONSIDERATIONS AND CONFIDENTIALITY

Clinicians working with youth in emergency psychiatric settings should be familiar with the laws and institutional regulations that govern emergency psychiatric treatment and hospitalization and also those that apply to the evaluation and treatment of minors. Many states allow for emergency psychiatric evaluation and treatment of a minor without a parent’s consent, and several allow adolescents to access outpatient psychiatric care without the parent’s knowledge or consent. If a child requires hospitalization, each state has statutes that dictate a standard for psychiatric hospitalization, generally differentiating between voluntary, involuntary, and emergency or diagnostic admissions. When working with minors, these laws generally dictate that a parent or guardian can hospitalize a child or adolescent under a “voluntary” admission, even without the minor’s assent, and often provide a standard by which the decision to hospitalize a child or adolescent can be made without the parent’s consent. Importantly, separate consent is commonly required in order to treat a hospitalized youth with medication. If parental rights have been surrendered or terminated, a foster care or state child welfare agency may have a court order providing them with the legal authority to provide consent for a child. States also have procedures to bypass consent if a parent or guardian cannot be reached or is refusing to consent to treatment deemed essential to the child’s well-being. Clinicians working in the ED should know these statutes as they apply in their area, as well as the local and institutional policies for consent and hospitalization.

Clinicians should also be familiar with mandated reporting laws for cases of suspected physical or sexual abuse or other maltreatment. If a patient reports serious intent to harm another person, the clinician has a responsibility to warn this individual, which supersedes the patient's right to confidentiality. Navigating the child's confidentiality vis-à-vis their parents can also be complicated. If the child is in imminent danger or a danger to others if the parent is not notified, the clinician should tell the parent, but first should attempt to understand the child's desire for secrecy. Often a child fears the parent will react with reprisal, anger, or distress and may be able to share with the parent with the clinician's support and guidance.

MODELS OF CARE AND INNOVATIONS

In recent years, new developments and innovations have sought to enhance and improve the quality of care for youth with mental health emergencies. Medical EDs have dedicated space with specialized behavioral health staff, and clinical pathways to standardize assessment, intervention, and disposition have been implemented. Hospitals have developed specialized youth psychiatric EDs modeled on adult psychiatric EDs, such as the Comprehensive Psychiatric Emergency Program (CPEP) model. These programs allow for a 3- to 5-day period of extended observation and active treatment in a specialized psychiatric care environment. They seek to stabilize acute psychiatric symptoms and thus avert the need for inpatient psychiatric hospitalization. Telepsychiatry has allowed child and adolescent psychiatrists to provide emergency mental health care to youth in EDs without access to in-person child and adolescent psychiatry staffing. Other service developments offer alternatives to ED visits. Mobile crisis programs, triage phone lines, and psychiatric triage teams provide youth with immediate and effective mental health care in the community. Intensive community-based treatment programs, such as MST or DBT, provide youth and families with a high level of outpatient support and access to clinicians for emergency coaching. These developments have improved the quality and raised the standards of care for youth experiencing mental health emergencies. As the number of mental health–related ED visits among youth continues to rise, investment in training, resources, and new innovations should seek to continue to improve the quality of psychiatric emergency care for children and adolescents.

CONCLUSION

Good ED care for children in psychiatric crisis means an accurate, developmentally informed diagnosis and formulation, stabilization of the crisis, and a treatment plan that helps the child and family to overcome stigma and systems barriers to access the right care. The practical challenges of connecting a patient to appropriate treatment should not be underestimated either. If a patient requires inpatient hospitalization, it can be difficult to find an open bed on a psychiatric unit for children and adolescents, but treatment on an adult unit or "boarding" in pediatrics should be avoided as both can be countertherapeutic. If the child will be waiting in the ED for several days before an appropriate inpatient bed is available, the ED provider should begin treatment (therapy or medication) to the degree that is possible in the ED.

When a patient is safe for discharge, the ED clinician should make every effort to connect the patient to an outpatient provider, not just give the parent a phone number for a provider or for their insurance panel. Connecting to outpatient care can be a very difficult and lengthy process and some parents cannot navigate the system due to insurance issues or the parent's own cognitive or language difficulties. Providing the patient with an actual appointment for follow-up has been shown to decrease future dangerous behaviors and so is crucial for the safe discharge of high-risk patients. ED clinicians should also familiarize themselves with case management services; child welfare services; community supports such as family resource centers; social services within the school, shelter, and family court systems; and respite and crisis services available through the state or city mental health, child welfare, or developmental disabilities services providers. These additional services can be crucial for avoiding a repeat presentation to the ED, particularly if psychosocial or family factors have influenced the current symptoms.

Genetics in Child Psychiatry

GIL D. HOFTMAN, M.D., PH.D., JAMES T. MCCRACKEN, M.D., AND ERIKA L. NURMI, M.D., PH.D.

One of the primary goals of human genetics is to identify DNA sequence variations that impact the onset and progression of human disease. Individual susceptibility for almost all psychiatric conditions is driven, at least in part, by genetic variation. Before the draft of the human genome in 2000 and subsequent completion of the Human Genome Project (HGP) in 2003, the role of genetics in medicine and psychiatry primarily focused on the identification of single-gene mutations that played causative roles in relatively rare Mendelian diseases such as neurofibromatosis, Huntington disease, and tuberous sclerosis. However, classic genetic approaches for Mendelian disease failed when applied to most common human diseases (e.g., heart disease, diabetes, asthma), including neuropsychiatric disorders. These common disorders often have high heritability, which is the proportion of variation in a population trait that can be attributed to inherited genetic factors (see Table 36–1). However, common disorders, despite high heritability, are complex in nature and caused by the hypothesized interaction of multiple genetic and environmental influences. While the HGP provided scientists with the 3 billion bases of primary DNA sequence comprising the human genome, assembling the puzzle pieces of complex genetic disease requires an understanding of human variation, DNA regulation, and other complexities that remains incomplete (see Limitations).

Fueled by continuing rapid technologic advances along with the efforts of large consortia (e.g., Psychiatric Genomics Consortium) and collaborative projects (e.g., ENCODE, PsychENCODE, 1,000 Genomes and International HapMap Projects), the amount of available genomic information has exploded over the past two decades. Identifying susceptibility genes underlying psychiatric illness has proven more vexing in psychiatry than for complex diseases in other areas of medicine (e.g., hypertension, inflammatory bowel disease, diabetes, cancer). One barrier to these efforts is the phenotypic complexity of psychiatric illness and the likelihood that most categories of psychiatric illness, as classified in the DSM-5, are heterogeneous in nature. In addition, most studies aimed at identifying susceptibility genes underlying psychiatric illness have been underpowered and suffered from hypothesis-driven bias. International consortia with growing sample sizes employing hypothesis-free genome-wide approaches have begun to identify multiple risk loci for neuropsychiatric disorders. These studies have highlighted the substantial overlap between categorical DSM diagnoses and implicate common risk pathways for susceptibility spanning traditional diagnostic boundaries. Recent research directions, such as the NIH Research Domain Criteria (RDoC), attempt to characterize psychiatric illness on dimensional and neurobiologic measures that may more accurately reflect underlying biology.

One major challenge remains to leverage the wealth of available data to advance the current understanding of genetic influences in mental illness, to ground these findings in neurobiology across development, and to make them clinically actionable. Such knowledge, once in hand, should provide opportunities for improved diagnosis, treatment, and prevention. Therefore, characterizing the relationship between DNA sequence variation and illness predisposition will likely help identify foundational processes of biologic pathophysiology and provide targets for novel strategies for prevention and treatment. Despite the complexity of childhood- and adolescent-onset neuropsychiatric disorders, clear progress has been and continues to be made, and that will be a key focus of this chapter.

Genetic information is also being applied in other areas to advance medicine and psychiatry. Knowledge of genetic background for treatment selection and the impact of genetic variation on drug response is referred to as *pharmacogenomics* or *pharmacogenetics.* Such fields advance the promise of “precision medicine”—the personalization of treatment based on genetics and other individual factors, which in other areas of medicine has yielded important, widely applied improvements in clinical care. While psychiatry lags behind in providing clinically actionable findings, public and professional enthusiasm for using genetic information to guide prescribing urges the field forward.

With the continued rapid advances in technologic, computational, and statistical methods in genetics, it is likely that genetic information will become even more important in understanding and diagnosing psychopathology, and in directing treatment recommendations. Psychiatrists need to appreciate the nature of the genetic discoveries as they emerge and to understand how to interpret and apply them in their practice; to do so requires basic knowledge of the research methods applied and the strengths and limitations of these findings. An update on current evidence in the genetics of childhood-onset psychopathology forms a needed background. The goal of this chapter is to highlight progress in genetic research on the etiology of pediatric-onset mental illness as it points to future opportunities to inform clinical practice and treatment practices.

THE GENETIC BASIS OF PSYCHIATRIC DISEASE

DNA Variation and Contribution to Disease Risk

In each individual human genome, there are millions of DNA variants, known as *polymorphisms*. Most changes appear to be neutral with respect to human illness but likely are critical for the diversity, robustness, and evolution of the human species. The earliest appreciated disease-associated genetic variations were cytogenetically visible interchromosomal translocations that disrupt or delete genes or regulatory elements, thus contributing to disease. More recently, large *segmental duplications* (SDs) or *copy number variations* (CNVs), involving extensive duplicated, repeated, inverted, or deleted segments of DNA larger than 1 kilobase (KB) in size, are observed commonly in affected and unaffected individuals. When certain CNVs are observed repeatedly in a population of individuals with a disease, the CNVs can point to disease-causing loci in the genome, such as those CNVs producing the Prader–Willi syndrome (15q11–q13 paternally derived deletions), some cases of syndromic autism (15q11.2–q13 maternal duplications), and William syndrome (7q11.23 deletion). Whereas gross chromosomal derangements typically affect multiple genes and produce rare but characteristic syndromes, subtler variations are more likely to be involved in complex disease susceptibility. CNVs are likely to contribute to disease through changes in gene dosage or disruption of genes or regulatory elements in the genome.

Table 36–1.
Definitions of Key Terms Used Throughout the Chapter

ATAC-seq	Identifies regions of the genome that are not histone bound in cell nuclei and are open to gene regulatory processes.
Common variant	A polymorphism with a minor allele frequency >1% (occurs in >1% of the population).
Copy number variant (CNV)	Structural chromosomal variants typically greater than 1 kilobase in size.
DNA Microarray	A small glass slide spotted with short DNA probes. Pieces of sample DNA hybridize to the chip and then are detected by scanning software. Chips can contain approximately 1.8 million different genetic markers.
Genome-wide association study (GWAS)	A test of whether particular alleles at SNP markers spanning the entire genome are associated with disease, traits, or other phenotypes of interest. A GWAS is most often conducted using chip microarrays in many (tens to hundreds of thousands) of individuals.
Heritability	A statistic that measures how much of the variation of a trait can be attributed to variation of genetic factors. It can be estimated by comparing individual phenotypic variation among related individuals in a population, by examining the association between individual phenotype and genotype data, or by modeling summary-level data from GWAS.
Hi-C	A chromosome-conformation capture

	method that can capture genomic regions that are near each other in cell nuclei. Hi-C does this in an all-interactions-to-all-interactions manner.
Liability-Threshold Model	A large number of variables (e.g., genes) is summed to create a risk score; the observed outcome is determined by whether that risk score is larger or smaller than a threshold (e.g., having or not having a SCZ diagnosis).
Linkage Disequilibrium (LD)	The nonrandom association of alleles at different loci due to recombination interacting with selection, mutation, and genetic drift.
Pleiotropy	Genes that affect multiple traits or increase risk for multiple disorders. For example, many of the same genes increase the risk for SCZ, BIP and ASD.
Polygenicity	A trait that is influenced by multiple genes or a disorder that is influenced by many genes of small individual effects. For example, thousands of genes, each with small effect, increase the risk for SCZ.
Polygenic Risk Score (PRS)	An estimate of an individual’s genetic liability to a trait or disease, calculated according to their genotype profile and relevant GWAS data.
Pharmacogenetics	How variation in a single gene influences the response to a single drug.
Pharmacogenomics	How the entire genome influences drug

	responses.
Quantitative Trait Loci (QTL)	Regions of DNA (loci) associated with variation of a particular trait or phenotype. For example, expression QTLs (eQTLs) identify genetic predictors of gene expression.
Rare Variant	Alternative forms of a polymorphism that are present with a minor allele frequency of <1%.
RNA Sequencing (RNA-seq)	Identifies the amount of all RNA molecules in a cell or tissue. Can also capture splicing and isoform-level information.
Single Nucleotide Polymorphism (SNP)	Variation at a single position (single base or nucleotide) in a DNA sequence.
Whole Exome Sequencing (WES)	A type of genome sequencing focused on protein-coding parts of the genome (~3%); good for finding gene-disrupting rare variants.
Whole Genome Sequencing (WGS)	Resequencing of the genome can identify all kinds of genetic variation in concept.

The contribution of CNVs to complex psychiatric illness is becoming increasingly appreciated in recent years. CNVs in aggregate are common (about 12% of the genome) and often polymorphic, with individuals carrying from zero to many copies of a given segment of DNA. As of 2019, there are 6,450 CNVs annotated in the human genome. Small DNA stretches that are deleted or inserted, collectively referred to as *“indels,”* are even more frequent, with more than 450,000 annotated indels in the human genome. CNVs are now understood to represent another genetic mechanism contributing to complex disease risk. For example, the DiGeorge/velocardiofacial syndrome (22q11.2 heterozygous deletion CNV) increases the odds of schizophrenia (SCZ) by about 50-fold compared with the general population. When compared to typically developing controls, total CNV burden is elevated in individuals with autism spectrum disorder (ASD) and SCZ. Although not all CNVs are pathogenic, disease-associated CNVs are larger and more likely to encompass gene-rich regions of the genome.

The simplest and most common type of individual genetic variation is the *single-nucleotide polymorphism* (SNP), widely employed in genetic studies. SNPs are changes of a single DNA base pair (e.g., adenine [A] to guanine [G]) that occur in approximately one per every 1,200 bases throughout the genome. Smaller indels and SNPs can influence disease through more targeted changes in individual genes. SNPs can directly alter protein structure through changes that alter amino acid sequence (nonsynonymous changes) in the gene product or distort start or stop signals. Even synonymous (silent) polymorphisms that do not alter amino acid–coding potential can influence RNA stability, splicing, targeting, editing, and efficacy of translation—many of the effects of these synonymous variants are unknown. Although noncoding changes are often overlooked due to presumed lack of function, they can exert powerful effects on the regulation of gene expression and transcript processing, as illustrated by the noncoding risk alleles described in macular degeneration and Crohn disease. Recent technologic advances have allowed for deeper interrogation of DNA regulatory elements, opening the door to studying and understanding noncoding regions of the human genome. For most mental illness, genome-wide studies have suggested an underlying genetic architecture consisting of both common ancestral alleles, each of which carries a small disease risk, and rare, highly penetrant mutations, that if present, are likely to result in disease.

Finding Risk Genes

Common risk variants are challenging to identify due to their small effect sizes and presence in healthy people, while causality of rare risk variants is difficult to prove due to the low signal-to-noise ratio. In both cases, very large sample sizes are needed, but discrete technologies are best suited to uncover common versus rare variants. The basic strategy behind studies aimed at disease gene discovery is to identify regions of the genome that are shared between affected individuals; the genes that underlie the disease must reside within these shared regions.

Neutral polymorphisms, although not directly contributing to the disease phenotype, can serve as markers for functional risk alleles since polymorphisms are not inherited independently but in large DNA blocks, a phenomenon known as *linkage disequilibrium* (LD). LD can persist for substantial distances across a chromosome and for numerous generations but decay as a function of the rate of recombination between homologous chromosomes. Therefore, it is not always necessary initially for an investigator to genotype a risk allele directly to find association with disease but merely to genotype one of the often many markers “linked” with the risk allele. Although an associated marker may have no direct role in disease etiology, it is present on an ancestral portion of DNA that also contains the disease locus and can thereby pinpoint the genomic location of the disease allele.

Two major shifts in the psychiatric genetics field are responsible for recent success in finding risk genes for mental illness after decades of struggle. First the development of genome-wide, high-throughput technologies enabled affordable, high-resolution data to be generated on large numbers of samples. In parallel, sufficiently large databases began to be collected due to the formation of large, worldwide collaboratives sharing tens to hundreds of thousands of patient samples. Modern successful genome-wide approaches, such as genome-wide association mapping, copy-number variant mapping, polygenic risk analyses, and whole genome or exome sequencing, overcame the limitations of and thus have supplanted prior limited gene-finding strategies like linkage analysis and candidate gene studies.

Genome-Wide Association Studies. In the new millennium, microarray (“gene chip”) technology has made ambitious GWAS possible; chips are available that can affordably assay millions of SNPs simultaneously. Given sufficient sample sizes, GWAS effectively detects common risk variants of small effect. Since only common, known SNPs are included on arrays, however, GWAS unfortunately, fails to capture the contribution of rare or novel variants. Currently, the consensus *P* value for significance in GWAS studies is set at 5×10^{-8}, correcting for the 50,000 predicted false positives that occur when a million tests are performed. While many psychiatric GWAS fail to meet this stringent level of significance, several large consortia have been successful by recruiting tens to hundreds of thousands of participants.

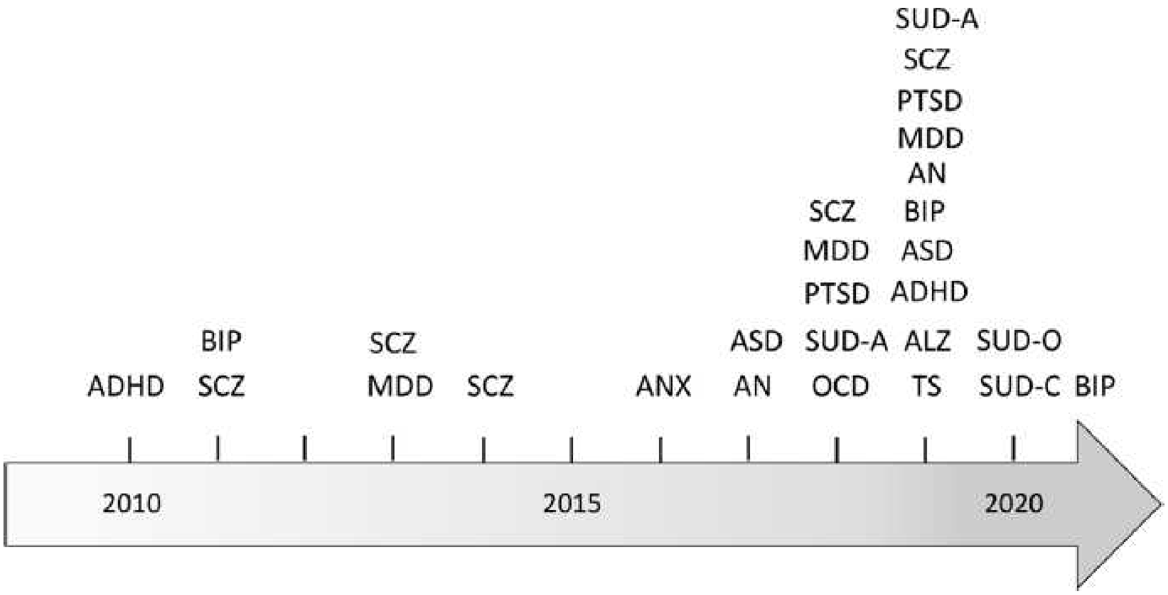

FIGURE 36–1. Timeline of recent key GWAS publications in psychiatric disorders since 2010. ADHD, attention-deficit/hyperactivity disorder; ALZ, Alzheimer disease; AN, anorexia nervosa; ANX, anxiety; ASD, autism spectrum disorder; BIP, bipolar disorder; MDD, major depressive disorder; OCD, obsessive-compulsive disorder; PTSD, posttraumatic stress disorder; SCZ, schizophrenia; SUD-A, alcohol use disorder; SUD-C, cannabis use disorder; SUD-O, opioid use disorder; TS, Tourette syndrome. (Data from Psychiatric Genomics Consortium. 2023. https://pgc.unc.edu/for-researchers/download-results/)

The first overwhelmingly successful GWAS in psychiatry examined SCZ in adults and provided a proof-of-concept that large enough sample sizes are indeed able to identify common risk variants of modest effect in psychiatric disease. Due to the cooperation and sharing between several multisite initiatives, tens of thousands of individuals with SCZ were analyzed in these studies. These initial promising results were further expanded by the Schizophrenia Working Group of the Psychiatric Genetics Consortium (PGC), who conducted a meta-analysis of 49 independent datasets totaling 34,241 cases and 45,604 controls, as well as 1,235 parent–offspring trios. This well-powered meta-analysis produced 128 statistically independent associations between individual SNPs and SCZ diagnosis at 108 loci (including 25 previously reported associations and 83 novel associations). Of interest, at least 75% of these loci contained one or more protein-coding genes, many of which were involved in synaptic plasticity and dopamine (DRD2), glutamate (GR1A1, GRIN2A, GRM3), and calcium (CACNAC1C, CACNA11, CACNB2) signaling pathways.

Since this original success, several other consortia have published similar successes in bipolar disorder (BIP), major depressive disorder (MDD), attention-deficit/hyperactivity disorder (ADHD), and recently ASD, while initial publications for many other disorders such as obsessive-compulsive disorder (OCD), Tourette disorder (TS), anxiety disorders (ANX), and substance use disorders (SUD) show promise with increasing sample sizes (Fig. 36–1). Interestingly, cross-disorder GWAS have revealed loci that span diagnostic borders, demonstrating effects in multiple psychiatric categorizations (e.g., SCZ and BIP, or ASD, ADHD, BIP, MDD, and SCZ; Table 36–2). These cross-phenotype risk genes imply a likely common underlying mechanism for certain aspects, or dimensions, of psychiatric disorders or the presence of resilience genes that confer protection against mental illness.

A substantial leap in pediatric psychiatric genetics occurred in 2019 when the first successful GWAS for ADHD, ASD, and anorexia were published. A GWAS of over 20,000 individuals with ADHD and 35,000 controls identified 12 genome-wide significant loci. Strong genetic overlap of ADHD diagnosis with population-wide cognitive traits supported the evolving conceptualization of categorical mental illness diagnosis lying at the far end of spectrum within the population (Fig. 36–2). A study published the following year showed that genetic risk for ADHD does not vary between adult and pediatric ADHD populations, underscoring the neurodevelopmental nature of the disorder. A similarly sized GWAS in ASD identified five genome-wide significant loci. Interestingly, common variants in ASD identified by GWAS align well with prior whole exome sequencing (WES) studies, highlighting high-confidence risk genes involved in chromatin regulation and neuronal and synaptic development and function. This study also supported the hypothesis that distinct genetic architecture plays a role in different ASD subtypes. In line with the findings of the increased role of large, damaging CNVs in ASD with intellectual disability, the higher functioning ASD subtype was more familial and associated with higher IQ and educational attainment in this large GWAS. GWAS of nearly 17,000 patients with anorexia and 55,000 controls reported 17 genome-wide significant loci with striking face validity, implicating risk genes impacting both psychiatric and metabolic factors. Aside from the above exceptions, the majority of GWAS for pediatric psychiatric disorders have resulted in only suggestive associations, most likely due to modest sample sizes. Other child-focused GWAS, such as those examining more dimensional traits such as “behavioral disinhibition” and “preschool internalizing problems” have again shown several loci approaching genome-wide significance. PGC Working Groups are currently collecting childhood-onset samples to facilitate large GWAS of the magnitude of those successful in adults.

Table 36–2.
Recent Large GWAS, CNV, and WES Studies Across Psychiatric Disorders

	GWAS (Common variants)			CNVs (Copy Number Variants)				WES (Rare Variants)			
Disorder	**Case N**	**Control N**	**N GWAS loci**	**Case N**	**Control N**	**Trios/ quads**	**N CNV loci**	**Case N**	**Control N**	**Trios/ quads N**	**N Genes**

GWAS loci are reported from the largest SNP-based studies. Loci enriched for rare copy number variants (CNVs) are reported from studies with >3,000 cases and controls. Individual genes associated with rare coding variants are reported from exome-sequencing studies with >3,000 cases and controls or >500 proband-parent trios.

ADHD, attention-deficit/hyperactivity disorder; AN, anorexia nervosa; ASD, autism spectrum disorder; BIP, bipolar disorder; MDD, major depressive disorder; OCD, obsessive-compulsive disorder; SCZ, schizophrenia; TS, Tourette syndrome.

Anxiety Disorder
Categorical Model: Anxiety Disorder Diagnosis

FIGURE 36–2. Dimensional versus categorical models of mental illness. Genetic loading in the population can be described dimensionally as a neurotic temperament or categorically as an anxiety disorder. Genetic risk for an anxiety disorder exists on a spectrum in the population, from low to high genetic loading. Neurotic temperament is a personality measure that captures anxiety risk dimensionally. Scores on temperament batteries reveal a distribution of individuals ranging from low to high neuroticism. A categorical disease model is overlaid by clinical medicine, where anxiety disorder is defined by impairment in functioning and distress. Individuals in the population are classified as either affected or unaffected. In uniting these two frameworks, increasing genetic risk produces higher neuroticism across the population, and at a defined threshold, anxiety disorder criteria are met.

Polygenic Risk Analysis. In addition to identifying discrete risk variants, GWAS can also inform genetic architecture and heritability. SNP heritability (h^2 SNP), the variance explained by SNPs, can be estimated from GWAS data. Polygenic risk scores (PRS) can be constructed to measure the variance explained collectively by common variation across samples and to test for genetic overlap between traits or shared risk between disorders. A PRS analysis is performed by selecting all of the SNPs meeting a given significance threshold for a trait of interest in a discovery sample and then testing whether this collective set of selected SNPs can also predict a phenotype in an independent replication sample. Using PRS, investigators can assess the genetic relationship between mental disorders and underlying shared risk for psychiatric pathology. However, PRS analyses suffer from Eurocentric ancestry GWAS sample bias at this time. Thus, emphasizing inclusion of samples from populations with non-European genetic ancestry may allow PRS use to be more equitable in the future (see Health Equity in Genetics Research).

Copy Number Variation Analysis. Comparative genomic hybridization (CGH) is a microarray-based technology that can detect CNVs in the human genome rapidly and accurately. *CGH arrays* are glass slides spotted with thousands of probes, from short oligonucleotides to hundred-megabats clone inserts, spanning the genome or focused on a genomic region of interest. Genomic DNA from a test subject and a reference sample are differentially labeled and then cohybridized to the array. Differences in hybridization signals between the test and reference sequences can be detected and decoded to reveal deletions or duplications relative to the reference sample. This method can be used to search for *de novo* (new, noninherited) CNVs in disease populations. CGH has also been used to identify polymorphic CNVs that can be tested for association with disease. Given that local SNPs are frequently in LD with CNVs, it is possible to test association at known CNVs by using nearby SNPs, bypassing the need to measure specific CNV genotypes directly. As an alternative to CGH, GWAS chips can be analyzed for fluorescent signal strength to similarly identify and quantitate CNVs, with increased signal across many adjacent SNPs pinpointing a deletion and increased signal reflecting a duplication.

CNV studies using these microarray-based methods have successfully revealed novel submicroscopic CNVs using advanced computational CNV-predicting algorithms present in populations with intellectual disability, ASD, and SCZ (see Table 36–2). CNVs have been detected in patients with sporadic ASD at 10 times the frequency in controls, and many CNVs are significantly associated with ASD. For this reason, microarray and Fragile X testing is now standard of care for ASD. These methods produce a distinct molecular diagnosis in over 20% of children tested.

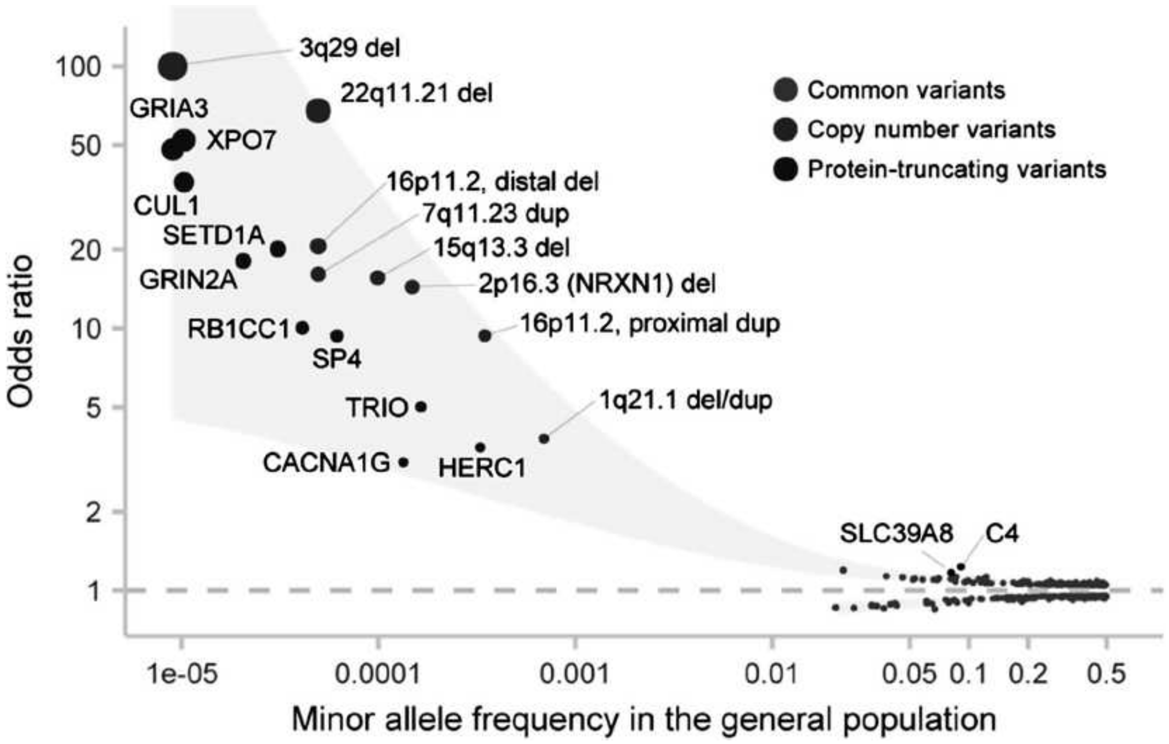

FIGURE 36–3. Inverse relationship between risk variant effect size and frequency. Example plot showing the gradient of differences in odds ratios among common, copy number, and rare variants in SCZ risk. Common variants typically increase the odds for SCZ by one- to twofold, whereas CNVs and rare variants can increase the odds for SCZ by 20- to 100-fold. Examples highlighted in this figure include common variants like complement C4, recently shown to be associated with SCZ with biologic plausibility given its hypothesized role in synaptic pruning; CNVs like 22q11.2 deletion syndrome, long associated with increased risk for SCZ; and rare protein-truncating variants like glutamate and calcium ion channel subunits (GRIA3, GRIN2A, and CACNA1G). (Adapted from Singh T, Neale BM, Daly MJ. Exome sequencing identifies rare coding variants in 10 genes which confer substantial risk for schizophrenia. *medRxiv*. 2020.09.18.20192815. doi: 10.1101/2020.09.18.20192815. https://creativecommons.org/licenses/by/4.0/.)

NV studies have also shed light on biologic processes that are affected in SCZ. Inherited and *de novo* CNVs associated with SCZ more frequently contain genes involved in neurodevelopmental pathways, encoding proteins that function in synaptic architecture, calcium signaling, and glutamatergic neurotransmission. In general, SCZ-associated CNVs have large individual effect sizes but are extremely rare in the population, whereas associated SNPs have small individual effect sizes but are common in the population (Fig. 36–3). The aggregate effect of both CNVs (*de novo* and inherited) and SNPs must be considered in order to fully understand genetic risk for psychiatric disease. In addition, smaller *de novo* CNVs have also been implicated in BIP and ADHD, but at a much lower rate and reduced overall genetic burden compared to ASD and SCZ. Table 36–3 summarizes recurrent CNV loci and their association with psychiatric illness.

Table 36–3.
Summary of Copy Number Variation Associated with Psychiatric Disorders

Locus	Copy Number Change	Disease Association
1q21.1	Deletion/duplication	SCZ, ID, ASD, ADHD
2p16.3	Deletion	SCZ, ID, ASD
3q29	Deletion	SCZ, ID, ASD
7q11.2	Duplication	SCZ, ID, ASD, ADHD, Anxiety
7q36.3	Deletion/duplication	SCZ, ID, ASD
15q11.2	Deletion	SCZ, ID, ASD, ADHD, OCD
15q11–13	Duplication	SCZ, ID, ASD
16p11.2	Deletion/duplication	SCZ, ID, ASD, ADHD, Anxiety, Mood
16p13.11	Duplication	SCZ, ID, ASD, ADHD
17q12	Deletion	SCZ, ID, ASD
22q11.2	Deletion	SCZ, ID, ASD, ADHD, Anxiety, Mood, VCFS
Xq28	Deletion/duplication	ASD

SCZ, schizophrenia; ID, intellectual disability; ASD, autism spectrum disorder; ADHD, attention-deficit/hyperactivity disorder; VCFS, velocardiofacial syndrome.

Genome Sequencing. While GWAS approaches are well suited to examining common genetic variation, genome sequencing studies can identify rare variation leading to disease. In the past decade, the advent of massively parallel sequencing made exome (protein-coding regions of the genome) and whole genome sequencing (WGS) possible. This technology generates millions of overlapping short reads from a DNA template that are assembled and aligned using a reference genome. By comparison to the reference genome, software is used to call genotypes at millions of known and novel variants across the sequenced genome. Since healthy individuals have been shown to carry tens of thousands of novel variants and hundreds of damaging mutations, the signal-to-noise obstacle presented by genome sequencing is staggering. One successful strategy limits the analysis to *de novo* variation by comparing proband to parent genomes. Three independent groups simultaneously published scans of *de novo* variation in ASD in 2012 (see Table 36–2). Collectively, these studies revealed that highly disruptive (nonsense and splice-site) *de novo* mutations in brain-expressed genes are associated with ASD and carry large effects. These *de novo* variants are overwhelmingly paternal in origin (4:1 bias) and positively correlated with paternal age. Multiple independent observations of *de novo* variants within the same gene among unrelated probands and across studies reliably identified several risk genes, including genes involved in sodium transport (*SCN1A, SCN2A*), chromatin remodeling (*CHD8*), and axon guidance (*NTNG1*).

Functional Genomics. Over the past decade, numerous technologic advances have been required to convert the single locus workflow into an integrative functional genomics approach. For example, genome-wide catalogs of functional activity have been generated (e.g., ENCODE project). More recently PsychENCODE has followed suit to generate maps of histone modifications, transcription-factor binding, chromatin assembly, and additional regulatory annotations across brain regions and cell types. For example, just as WES is able to uncover rare variants, other methods like Hi-C and ATAC-seq allow for chromatin capture and interrogation of chromatin state and epigenetic profiling, respectively (Fig. 36–4). These approaches facilitate an understanding of how genetic variation impacts not simply the protein sequence but also the regulation of gene expression. Additionally, overlap between GWAS and functional data allows for more detailed clues about cell type contributions to disease pathogenesis and accelerates the discovery of locus-specific disease mechanisms. There have also been efforts to map quantitative trait loci (QTLs), which are regions of DNA associated with specific traits, across hundreds of individuals and tissues by the Genotype-Tissue Expression (GTEx) consortium. Although QTL approaches can implicate a haplotype in a molecular or cellular phenotype, they cannot identify specific causal variants. Additionally, newer technologies like massively parallel reporter assays (MPRAs) and clustered regularly interspersed short palindromic repeats (CRISPR) genome editing can support functional characterization of specific sequence alterations at scale.

FIGURE 36–4. Functional genomics: from genes to neurobiology. From left to right, methods used to elucidate genetic, functional, and cellular architecture underlying psychiatric illness are shown. For genetic architecture, methods include whole genome sequencing (WGS), whole exome sequencing (WES), and GWAS. Examples of functional architecture include RNA-seq and chromatin-directed assays like Hi-C and ATAC-seq. Cellular architecture is probed using gene pathways, gene networks, and regulatory regions in specific tissue types, cell types, and developmental stages. (Adapted from Sullivan PF, Geschwind DH. Defining the genetic, genomic, cellular, and diagnostic architectures of psychiatric disorders. *Cell*. 2019;177(1):162–183.)

Pathway Analysis. Individual common SNPs appear to confer only small effects on psychiatric phenotypes, and while they have larger effect sizes, disease-associated CNVs are rare in the population. Therefore, multiple risk alleles in combination are likely required for disease expression (Fig. 36–5). As the first successful studies identifying risk alleles in psychiatric illness have been published, common pathways impacting specific cellular or neurodevelopmental processes have emerged. Many studies now include pathway analyses to add functional relevance and validity to GWAS or sequencing results. Using bioinformatic and gene ontologic approaches (e.g., gprofiler which uses GO Gene Ontology, KEGG, and other databases), investigators can determine whether associated genes belong to particular gene networks or cellular processes above chance levels. Using these approaches, scientists can begin to build gene interaction networks based on a priori knowledge of gene function gleaned from the research literature. These data can inform the development of prediction models, generating testable hypotheses about how a particular risk allele might alter a biologic process to drive disease risk.

FIGURE 36–5. Hypothesized liability-threshold model with a focus on polygenicity and pleiotropy. The left panel represents Disorder A (in this example, ASD), and the right panel represents Disorder B (in this example, schizophrenia spectrum disorder). The left and right panels each have two individuals. Individual #2 does not reach the threshold for Disorder A. Each shape represents a risk gene (common or rare variant) for the disorder. The shapes combine additively, and when they cross a threshold, a person has the disorder. *E* represents environmental impact. Shapes shared across disorders represent pleiotropy. Poly Singh et al. medRxiv 2020 genicity is represented by multiple different shape types within an individual that add up to result in a disorder. Liability thresholds can be unique for different disorders. The size of each shape represents the relative risk contribution of each gene variant. (Adapted from Gandal MJ, Geschwind DH. Polygenicity in psychiatry-like it or not, we have to understand it. *Biol Psychiatry*. 2021;89(1):2–4.)

PHARMACOGENOMICS IN CHILD PSYCHIATRY

Identifying genes that predict treatment response or adverse effects can improve the safety, tolerability, and effectiveness of psychotropic medication. Thus far, most pharmacogenetic studies in adult psychopharmacology have been limited to investigations of single genes or small numbers of genes and frequently test only single variants within these genes for association with drug response. These candidate gene studies have provided inconsistent support for a variety of functional variants largely in neurotransmitter signaling genes. Given the lack of reproducibility and known biases undermining candidate gene studies, these results should be interpreted with caution until confirmed by hypothesis-free genome-wide methods and prospective designs. A notable exception is a large electronic health record survey of drug level and clinical outcome of escitalopram (Lexapro) treatment based on *CYP2C19* genotype. This study strongly supported the clinical validity and utility of incorporating *CYP2C19* genotype into clinical decision making.

While the current gold standard for finding common genetic variation, large-scale GWAS are a particular challenge for detecting pharmacogenomic phenotypes. Well-controlled clinical medication trials are limited in size by feasibility and cost. Population studies are complicated by the inherent heterogeneity of the sample and the use of imprecise self-report or electronic health record data. Combining existing samples also presents considerable obstacles due to differences in outcome measures, study protocols, and diverse populations. No genome-wide significant results emerged from several GWAS conducted for pharmacogenomic predictors of treatment response in adult psychiatry: a meta-analysis of 2,245 individuals of European ancestry with depression (STAR*D, GENDEP, MARS), a depression treatment study of citalopram (Celexa) in 865 adults by the International SSRI Pharmacogenomics Consortium (ISPC), a SCZ treatment trial of 738 subjects receiving multiple antipsychotics (CATIE), and a multiple treatment arm study of 458 patients with bipolar disorder (STEP-BD). GWAS for adverse effects have similarly failed to identify compelling signals in adult samples, including antidepressant treatment-emergent suicidality and metabolic, cardiac, and movement side effects of antipsychotics.

The few pharmacogenomic GWAS in pediatric populations have been more successful thus far. One success was found in a GWAS of antipsychotic-induced weight gain in youth, identifying a risk allele with face validity near the melanocortin 4 (MC4R) gene. When meta-analyzed with three replication cohorts, a genome-wide significant result was reported. GWAS data generated by the OCD Collaborative Genetics

Association Study (OCGAS) was used to examine self-reported positive response or nonresponse to serotonin reuptake inhibitors in 804 subjects with childhood-onset OCD; one SNP near DISP1, a gene involved in neurodevelopment, achieved genome-wide significance. Interestingly, enrichment pathway analysis of suggestive associations highlighted the potential roles of glutamatergic and serotonergic neurotransmitter systems. Several small GWAS of response to methylphenidate and stimulant-induced cardiovascular side effects in children with ADHD, however, failed to produce genome-wide significant results.

CLINICAL CORRELATIONS

The application of genetics in the practice of child psychiatry is in its infancy but is growing rapidly. As described below, genetic testing now has a recommended role in many clinical evaluations and in a growing number of treatment decisions. Given the expected expansion of knowledge in child psychiatric genetics, clinicians need to stay informed, as additional practice implications are sure to follow.

Diagnostic Genetic Testing in Current Psychiatric Practice

Published guidelines from the American Academy of Pediatrics and the American College of Medical Genetics both recommend CGH and GWAS analyses as a routine part of the evaluation of any child with suspected ASD and all children with intellectual disability in an effort to determine molecular diagnoses. In addition, these clinical guidelines include the recommendation for genotyping for the fragile X triplet-repeat mutations and identified mutations in the Rett syndrome *MECP2* gene. The guidelines note that girls with learning disabilities and suspected other developmental delays have been found to possess these mutations in the absence of full syndromic features. Children with macrocephaly should also be tested for mutations in the *PTEN* gene, given its role in growth pathways and association with head circumference. At present, estimates are that routine genetic testing in ASD, as well as intellectual disability, results in positive findings in as many as 20% of individuals.

Some centers have begun routinely obtaining WGS for suspected Mendelian disorders in place of high-density microarray testing for some patients, hoping to identify rare mutations not captured by arrays. Other centers are now collecting WGS data for every patient entering their medical system. With the expansion of clinical testing taking place, more and more patients will present with already available genome sequence data, challenging physicians to identify findings of clinical import. As a result, psychiatrists need to attempt to stay current with the research literature and develop facility with the many searchable genetic databases to aid their interpretations of patient information.

Pharmacogenomic Testing in Current Psychiatric Practice

Pharmacogenomic testing has unquestionably entered the clinical practice of child psychiatry. The U.S. Food and Drug Administration (FDA) has required the inclusion of pharmacogenomic information of clinical importance for over 30 psychotropics commonly used and encountered in mental health treatment. The FDA provides a comprehensive list of these labels on its website. The majority of pharmacogenomic labeling pertains to specific drug safety concerns associated with specific genotypes and their corresponding phenotypes. Arguably the most compelling example is the FDA recommendation for *HLA-B*1502* allele testing prior to prescribing carbamazepine (Tegretol) and oxcarbazepine (Trileptal) in patients of Asian ancestry. The *HLA-B*1502* allele appears to be primarily restricted to Asian populations and is strongly associated with increased risk for severe cutaneous adverse drug effects such as Stevens–Johnson syndrome (SJS). It has been found to be present in greater than 90% of individuals who developed SJS associated with carbamazepine. A majority of other pharmacogenomic considerations relate to genetically mediated drug metabolism differences associated with other safety risks.

Reflecting the growing appreciation of the importance of individual genetic differences in pharmacokinetics and drug distribution, the FDA approved the first pharmacogenetic test, the AmpliChip CYP450, in January 2005. Test results from this chip provide relatively comprehensive testing of well-defined, clinically relevant polymorphisms in two cytochrome P450 genes (*CYP2D6* and *CYP2C19*) that are known to be associated with large differences in the metabolism of many psychotropic medications. Polymorphisms in the genes encoding these enzymes commonly result in poor-metabolizer and ultrarapid-metabolizer phenotypes, producing extreme variability in circulating drug levels. An estimate of the United States’ annual treatment cost of adverse antidepressant reaction in CYP2D6 poor metabolizers was $420 million in 1999; consequently, some authors advocate the economic viability of testing CYP genotypes prior to antidepressant therapy. Current guidelines do not endorse standard genetic testing for antidepressants; however, testing is recommended for prescribing tricyclic antidepressants, as well as specific antidepressants from other classes. These guidelines, available at the Clinical Pharmacogenetics Implementation Consortium (CPIC) website, advise avoidance of tricyclic antidepressants in individuals with ultrametabolizer CYP2D6 status because of potential lack of efficacy and either avoidance or 50% dose reductions and monitoring of therapeutic drug levels in individuals with the “poor metabolizer” phenotype of CYP2D6 or CYP2C19. Similar guidelines are available for selective serotonin reuptake inhibitors (SSRIs). CPIC also published a guideline to assist with atomoxetine dosing in patients with ADHD. Importantly, CPIC review of the effects of CYP2D6 metabolizer status on treatment outcome revealed that a third of normal metabolizers will not achieve therapeutic blood levels of atomoxetine (Strattera) within the FDA-specified dosing range, and therapeutic blood monitoring may be beneficial in optimizing atomoxetine dose. Genotype-tailored treatment is routinely performed in many other areas of medicine (tamoxifen, warfarin, antineoplastics) and will continue to expand in relation to the safe and effective use of psychotropic therapies.

Numerous commercial entities have begun to offer a wider range of genetic “decision support tools (DSTs),” ostensibly to inform psychiatric practice. While several commercial testing providers have published data supporting their products, these studies do not evaluate individual tests but demonstrate that the whole package improves patient care when compared with treatment as usual. Unfortunately, proprietary algorithms are employed that cannot be validated externally. A few positive meta-analyses of the use of DSTs in adult psychiatry have been published but are based on poor-quality primary studies with substantial heterogeneity and mixed results. Problems with study design, posthoc outcome reporting, bias, test validity, and generalizability temper enthusiasm for positive findings. Furthermore, these studies are funded and analyzed, if not entirely conducted, by industry with major financial conflicts of interest. Prior to 2021, no data existed in pediatric samples, and the use of DSTs to guide pharmacotherapy for a variety of child mental health diagnoses was supported only by data from middle-aged women with depression who had failed at least one prior medication trial. The first randomized controlled trial of pharmacogenomic guided treatment compared to treatment as usual in adolescents with depression failed to show superiority. The one significant finding revealed that physicians receiving genetic data were less likely to prescribe an evidence-based treatment for depression in youth, demonstrating a common phenomenon whereby physicians inappropriately follow weak genetic guidance over the empirically driven evidence base. Clinicians should be aware that the supporting evidence for most pharmacogenetic testing is extremely limited and lacks the wider replication required before such tests can be considered “evidence-based.” Current responsible guidelines suggest consideration of *CYP2D6* and *CYP2C19* testing in adults with depression who have failed at least one prior adequate medication trial and HLA genotyping to prevent serious adverse events with carbamazepine and oxcarbazepine use. Results may inform which drugs to avoid or dose more cautiously in a given patient but currently cannot predict whether any medication will be effective. The FDA has issued several warnings against the use of DSTs in psychiatry. Similarly, the American Academy of Child and Adolescent Psychiatry cautions against the use of these products in child psychiatry in an online position statement.

LIMITATIONS OF CURRENT RESEARCH

Even with complete knowledge of the genetic architecture of a psychiatric disorder, deeper and actionable understanding requires a detailed understanding of the functional genomic and cellular architectures. Functional genomics approaches examine how implicated loci impact regulatory processes that influence gene expression and the functional coordination of these genes that influence biologic processes. Cellular architecture approaches target when and where these functional processes are operative within brain regions, layers, cell types (neuronal, glial, progenitor), and developmental stages (pre- and postnatal).

Understanding brain region, layer, and cell type specificity in a psychiatric condition may reveal the selective vulnerability of neuronal subtypes to brain injury and explain how despite exposure to a common insult, disease pathogenesis may reflect disrupted function in a specific subset of brain cells. For example, mutant huntingtin protein (encoded by the *HTT* gene) is widespread in Huntington disease, but striatal degeneration is disproportionately affected. Anoxia disproportionately leads to cell death of hippocampal CA1 pyramidal neurons compared with pyramidal neurons in other hippocampal subregions.

One barrier to identifying genetic susceptibility to psychiatric conditions includes the phenotypic complexity of psychiatric illness. Another is the lack of direct brain tissue accessibility over time within an individual across the course of psychiatric symptom development and progression. Additional key issues include polygenicity (many genes contribute small effects to a psychiatric disorder) of each psychiatric condition and pleiotropy (risk genes are shared across psychiatric disorders) that make causal links between susceptibility genes and the development of a psychiatric condition incredibly challenging (see Fig. 36–3). These numerous promising associations do not necessarily imply causation. Grounding genetic associations with functional data in autopsy-derived brain tissue, stem cells obtained from blood and skin, and live model systems will be critical for understanding their impact and contributions to causal mechanisms responsible for illness pathogenesis.

Ongoing challenges relate to disseminating lessons from high-quality science to the clinic while discouraging the implementation of untested strategies. The current state of the use of genetic data in clinical practice demonstrates this pitfall: (1) genetic testing is recommended in the evaluation of ASD and intellectual disability, but its use is woefully underutilized, and (2) commercial pharmacogenomic testing is widely available and often a primary factor in treatment when its utility is not yet established.

FUTURE DIRECTIONS

Advancing Technology, Computational, and Basic Neuroscience Methods

Emerging technologies and novel data collection and mining methods offer promising avenues forward. Digital technologies provide opportunities for real-time data collection, facilitating the incorporation of objective data collected by wearable devices to study both the momentary and longitudinal course of symptoms and behavioral domains. Electronic health record mining can deliver large databases of clinical information for scientific study. These avenues, in addition to continued subject recruiting across diverse populations, will supply ever-expanding datasets for analysis. Patterns and processes too complex for human appreciation can be detected by computational data-mining approaches like machine learning, leveraging advances in artificial intelligence. Once hypotheses are generated by analysis of big data, functional studies are needed to validate conclusions. Recent molecular tools to examine functional effects include MPRAs that can screen thousands of noncoding genomic regions simultaneously to test for functional effects, CRISPR (clustered regularly interspaced short palindromic repeats) assays that can manipulate genes in a fully developed organism, optogenetic technologies that can activate or suppress neural pathways in vivo, and single-cell multiomic integrative approaches that reveal the complex processes occurring in a single neuron.

The field of epigenetics attempts to understand the impact of experience (e.g., environmental influences) on the regulation and expression of genes. Early findings have already shed light on the mechanisms by which early childhood adversity can lead to risk for adult mental disorders (post-traumatic stress disorder, mood disorders) via methylation of genes involved in the stress–response system. Causal relationships are often a challenge for epigenetic conclusions; however, new approaches, such as Mendelian randomization, have begun to offer solutions. As epigenetic mechanisms are revealed, they are likely to point to novel prevention and treatment strategies that could be applied to youth and potentially alter the trajectory of their development and adaptation. Such exciting prospects should encourage close attention to this important area of psychiatric research.

Pediatric Populations

Genetic studies in pediatric samples are dwarfed by those conducted in adults. Furthermore, age-of-onset is often not obtained in adult samples and represents a missed opportunity. Interestingly, most childhood-onset neuropsychiatric disorders appear to be more heritable than similar adult-onset phenotypes, suggesting that research to identify genetic influences might be more fruitful in pediatric samples. Likewise, studies of genetic influences on treatment and prognosis may be more revealing in younger, treatment-naive subjects. As more adult-onset psychiatric disorders are increasingly being conceptualized as neurodevelopmental in nature, with identifiable prodromal and subclinical childhood manifestations, the study of such early phenotypes may represent genetic subgroups more tractable for etiologic investigations.

Precision Psychiatry

Precision medicine seeks to employ knowledge of individual differences to inform diagnosis, prognosis, and treatment. Over the coming decades, precision psychiatry will likely incorporate not only genetic but also molecular, biochemical, electrophysiologic, imaging, and behavioral biomarkers. Machine learning and other computer-driven approaches can be used to analyze biomarker data and develop data-driven, predictive algorithms that improve with experience. Digital phenotyping with smartphones and wearable sensors might also contribute to precision psychiatry.

As the adoption of clinical genetic testing expands, spurred by future technical and scientific progress, more and more genetic information will become available to clinicians. Many publicly available databases can be accessed by clinicians in their efforts to understand the possible role of genetics at the level of the individual patient, including the guidelines published by the FDA and CPIC, as well as information about specific genetic variants curated by the Pharmacogenomics Knowledge Base (PharmGKB).

Health Equity in Genetics Research

For most diseases, including psychiatric disorders, large-scale GWAS-aggregation efforts have been biased toward information from individuals of European ancestry. While many common risk alleles discovered in one population group are detectable in others, allele frequencies can vary substantially. Therefore, refocusing GWAS and sequencing studies on diverse populations will most likely generate a rich landscape of novel risk alleles.

The use of PRS to improve psychiatric disease outcomes via precision medicine remains one possible and practical area for the clinical translation of genetic risk. However, clinical implementation of PRS raises ethical and scientific challenges since PRS are many-fold more accurate in individuals of European ancestry than others due to Eurocentric GWAS biases. Thus, clinical uses of PRS today would benefit those of European descent at the expense of non-European populations. Critically, new research must prioritize greater diversity in genetic studies with early public dissemination of summary statistic findings to promote health equity and decrease disparities for those who are already most underserved.

Expanded Genetics Training for Mental Health Providers

As a field, psychiatrists should be able to critically appraise the evidence supporting genetic testing and pharmacogenetic/pharmacogenomic testing. Current clinical applications include estimating risk for psychiatric illness from family structure and epidemiologic studies, ordering and interpreting genetic tests for ASD and intellectual disability, and knowing when to consult genetic counselors and medical geneticists. Some anticipated novel clinical applications in the pipeline include estimating psychiatric risk with specific CNV and SNV information, ordering exome sequencing genetic tests for rare variants in SCZ and BIP, and applying genetic risk scores (e.g., PRS) to guide personalized psychiatric medicine. Covering basic principles of genetics, common and rare genetic variants, pharmacogenetics, epigenetics/gene expression, ethical and social issues in genetics, and principles of risk communication during psychiatry residency training may help bridge the education gap and increase confidence and comfort for future psychiatrists to address these issues clinically.

ACKNOWLEDGMENTS

This chapter represents an update and revision of previous chapters in this series, most recently by Meredith Hannan, M.D., Ph.D. from the last edition. We are indebted to Dr. Hannan for her work and retain much of her prose in this current edition.

Neuroimaging in Psychiatric Disorders of Childhood

FRANK P. MACMASTER, PH.D., KAYLA D. STONE, PH.D., SNEHA CHENJI, PH.D., AND DAVID R. ROSENBERG, M.D.

Over the last three decades, there has been a revolution in our understanding of the living human brain. The advent of brain imaging has allowed for noninvasive assessment of brain structure, function, and chemistry. Until the development of brain imaging, the investigation of the neurobiologic underpinnings of psychiatric illness in children was difficult. Indeed, for many years, the commonly held belief was that psychiatric conditions did not occur in pediatric populations. Brain imaging research has allowed us to move away from this era of skepticism by demonstrating that psychiatric illness does indeed affect children, and these illnesses often have clear neurobiologic underpinnings. The application of brain imaging to describe the biology of the illness can lead to improved diagnosis and innovative treatments. Moreover, the study of brain maturation may make it possible to find critical time periods during which brain abnormalities could lead to neuropsychiatric symptoms. The research findings may also indicate potential "targets" for treatment intervention.

This chapter has three sections. First, core brain imaging methods are described. Second, special considerations (such as sex, gender, and development) are addressed. Third, relevant findings from brain imaging studies of psychiatric disorders of childhood are summarized. Disorders include attention-deficit/hyperactivity disorder (ADHD), mood disorders such as major depressive disorder (MDD) and bipolar I disorder (BP-I), anxiety disorders, obsessive-compulsive disorder (OCD), post-traumatic stress disorder (PTSD), Tourette syndrome (TS), childhood-onset schizophrenia (COS), substance use disorders, feeding and eating disorders, autism spectrum disorder (ASD), and specific learning disorders including dyslexia. The purpose of this chapter is to provide an understanding of brain imaging in psychiatric disorders of childhood.

TECHNIQUES AND PRACTICAL CONSIDERATIONS

Neuroimaging Techniques

Thirty years ago, the study of the brain was largely limited to postmortem work. However, postmortem studies are not practical for developing an understanding of psychiatric disorders of childhood. Nearly all postmortem brains come from adults. Hence, they are confounded by age, chronic illness, and exposure to treatment. The application of brain imaging techniques has overcome this obstruction to facilitate progress in understanding the developing brain.

Morphology/Structure

Morphologic studies include the examination of the structure of grey and white matter. Computed tomography (CT) was the first imaging method to make routine the direct, in vivo, and noninvasive evaluation of the living human brain. In practice, magnetic resonance imaging (MRI) has replaced quantitative CT in brain research due to its improved resolution and tissue contrast (Fig. 37–1). Early studies in psychiatry began with more of a "radiologic" approach—that is, looking for the presence or absence of visible damage or lesions. An example of this is the link between MRI T2 hyperintensities in left frontal stroke and depression. These lesions can be observed with the naked eye. This approach was not adequate, as most psychiatric illnesses do not involve a visible lesion. Hence, the field focused on more quantitative methods.

A measure should be both valid and reliable. Measurement of biologic structures is challenging, as many parameters change with development and even over shorter periods of time. In the human brain, not all aspects are MRI-visible. This is critical when designing an experiment using MRI as the method. The effect must be of necessary scale to be detectable. However, the technology is continually improving. For instance, MRI techniques have been developed to examine cortical layers (2 to 4 mm thick) using MRI scanners operating at 7T. It may someday be possible to evaluate single cells in vivo using MRI-based technologies. In addition to the ability to be detected and measured, the structure must also be of clinical interest. In other words, it should be critically involved in a specific function associated with the psychiatric disorder in question.

The two principal steps in morphologic MRI studies are data acquisition and quantification. With both of these steps, bias, and error can diminish the validity of the study. Bias can obscure real effects or produce incorrect findings. Error is random variation. Both bias and error can reduce statistical power and result in erroneous findings. There is no single accepted method for reducing bias and error in each of the steps involved in MRI experiments. Furthermore, there is little consensus regarding how to properly perform anatomic quantification, with methods varying considerably. Due to inherent variation in regional brain volumes, it is accepted that large sample sizes are required to demonstrate even moderate effects between groups.

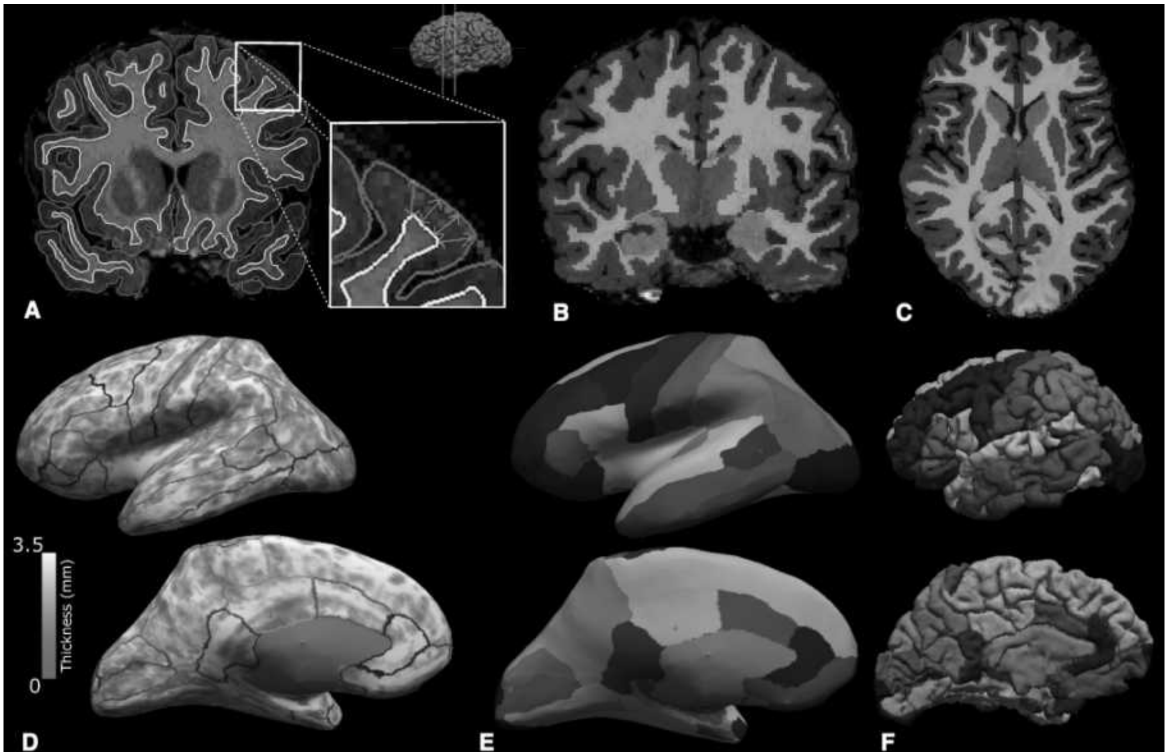

FIGURE 37–2. Cortical thickness and subcortical volume from a pediatric participant. Panels represent outputs from FreeSurfer. **A**: Outlines depict white matter edges (*yellow*) and pial edges (*red*) which enable calculation of cortical thickness. **B, C**: Coronal and axial views of subcortical volumes, respectively. **D**: Heat map representing cortical thickness across various brain regions. **E, F**: Sample parcellations using Desikan–Killany atlas showing inflated brain and gyri, respectively. (See eBook for color image.) (Courtesy Sneha Chenji, Ph.D.)

Grey Matter: Volume, Shape, Thickness, Area, and Gyrification. A “structure” should be distinct from its neighbors. Within the brain structure, there should be a common aspect to or resultant from the parts comprising the structure. This could be cell type, neurotransmitter receptor distribution, or function. For instance, caudate could be a descriptor because it has specific related functions and is contiguous spatially. When trying to understand the brain, you need to know where functionally specific structures are located, what function they perform, and how the distributed processing of that function is organized. The volume of a brain structure is reflective of the size, shape, and density of its parts. It is reasonable to assume that functional changes are reflected physiologically with changes in cellular composition and/or activity. Consequently, by examining the volumetric properties of a structure, one can make inferences about its functionality. Researchers may also study the shape of a brain structure and compare groups and conditions. The quantitative analysis of biomedical shape variation and shape change, while more complicated mathematically, offers useful information on two- and three-dimensional properties of structures that may be relevant to disease states. More recently, the investigation of cortical thickness, surface area, and gyrification (i.e., the pattern and degree of cortical folding) has become increasingly common in the study of pediatric psychiatric populations (Fig. 37–2). These approaches are typically automated and rely on established templates identifying structures and localization of differences.

White Matter Measures: Diffusion Tensor Imaging. Diffusion tensor imaging (DTI) is based on the MR signal resulting from the restricted movement of water in brain tissue. The fundamental architecture of white matter has the axons running in parallel bundles or tracts. This forces water molecules to move along the main bearing of the tract. This oriented dispersal pattern is termed anisotropic diffusion. The location, direction, and anisotropy of the white matter tracts can be measured, yielding metrics that enable investigation of in vivo white matter changes. Fractional anisotropy is a common scalar metric (ranging from 0 to 1) used to measure white matter integrity. It indicates the directional preference of water diffusion. Additional metrics such as axial diffusivity (diffusion rate parallel to the axon bundle) and radial diffusivity (diffusion rate perpendicular to the axon bundle) provide insight into white matter development including myelination and axonal packing (Fig. 37–3). These metrics can be used to measure individual tracts (e.g., superior longitudinal fasciculus) or can be used to measure the structural connectivity pattern of a brain circuit (e.g., using graph theory). DTI measures vary in different brain regions. For example, white matter in the frontal lobes may show lower anisotropy. This is due to the presence of crossing white matter fibers. Thus, careful consideration is required when choosing DTI parameters. Advances in diffusion imaging parameters enable delineation of crossing white matter fibers and provide further insights into intricate tracts such as in the frontal lobe. Myelin water imaging—which quantifies the fraction and relaxation parameters of water trapped in the lipid bilayers—has been applied in neurodegenerative conditions but could offer additional insight into childhood-onset neuropsychiatric disorders.

Chemistry

Brain imaging methods that evaluate brain chemistry may be more sensitive than structural imaging studies for identifying localized abnormalities in psychiatric illness. As indicated above, the radiologic hallmarks of psychiatric illness are often subtle, not typically visible to the naked eye, and require very sensitive methods of detection. Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) methods have been critically informative regarding the pathogenesis and mechanisms of treatment response of several neuropsychiatric conditions in adults. However, these techniques use ligands labeled with radiation, thereby increasing the risk of their use in children and adolescents. In contrast, MR-based techniques are free of ionizing radiation and, as such, have rapidly become the preferred means for examining neuroanatomy, blood flow, and chemistry in children. Novel methods, like 3D PET, do use less radiation and may become an alternative in the future.

Magnetic Resonance Spectroscopy. Magnetic resonance spectroscopy (MRS) measures chemicals in the brain. Although many nuclei with odd-numbered protons or neutrons, including phosphorus (^{31}P), carbon (^{13}C), fluorine (^{19}F), sodium (^{23}Na), and proton (^{1}H) compounds, can be detected using MRS, ^{1}H-MRS is the most commonly used technique, providing measures of the following: N-acetyl aspartate (NAA), a neuronal marker; creatine/phosphocreatine (Cr), involved in energy metabolism; choline compounds (Cho), membrane components; myo-inositol, a secondary messenger involved in signal transduction; and glutamate + glutamine (Glx), and γ-aminobutyric acid (GABA)—all of which occur in relatively high concentrations in the brain (Fig. 37–4). ^{31}P-MRS is the second most common approach in developmental populations. ^{31}P-MRS allows for the study of the products of membrane synthesis (phosphomonoesters [PMEs] like phosphoethanolamine and phosphocholine) and breakdown (phosphodiesters [PDEs] like glycerophosphoethanolamine and glycerophosphocholine), along with substrates of energy metabolism. The choice of MRS versus PET/SPECT measures of brain chemistry involves important trade-offs. First, MRS does not have the power to detect chemicals occurring at lower concentrations, such as monoamines, neuropeptides, opiates, and so on. Second, MRS has relatively poor spatial and temporal resolution as compared to that of PET. However, with data acquisition and spectral editing programs becoming increasingly sophisticated and the increases in magnetic field strength, striking improvements in the spatial and temporal resolution of MRS are being fulfilled.

Function

Functional Magnetic Resonance Imaging. The selection of functional magnetic resonance imaging (fMRI) versus PET/SPECT measures of cerebral blood flow also involves trade-offs. fMRI delivers excellent spatial resolution (1 mm or less) along with potentially superior temporal resolution (about 1 second) compared to the PET/SPECT approaches. Second-to-second temporal resolution is now possible with event-related fMRI. Unlike PET/SPECT, fMRI does not provide an absolute measure of cerebral blood flow. Rather, fMRI detects changes in blood oxygenation-level–dependent (BOLD) signal using a T2*-weighted sequence. It relies on the paramagnetic properties of deoxyhemoglobin to induce local changes in image intensity. Using carefully designed neurobehavioral paradigms during fMRI scans, BOLD signals can be used to generate a pattern of activation (Fig. 37–5). Early techniques involved contrasting task conditions with rest conditions to determine areas of activation. New analytical techniques allow for the quantification of “baseline” or “resting-state” blood flow using fMRI images. Initial techniques involved exploring changes in BOLD signal in a specific a priori region of interest (seed) relative to the whole brain (seed-based correlation analysis). More recent techniques use advanced approaches such as Independent Component Analysis (ICA) and graph theory metrics. These provide a model-free approach (no a priori seed) to explore whole brain networks at rest. The study of so-called resting-state networks offers an innovative method for determining differences in brain function between groups and conditions.

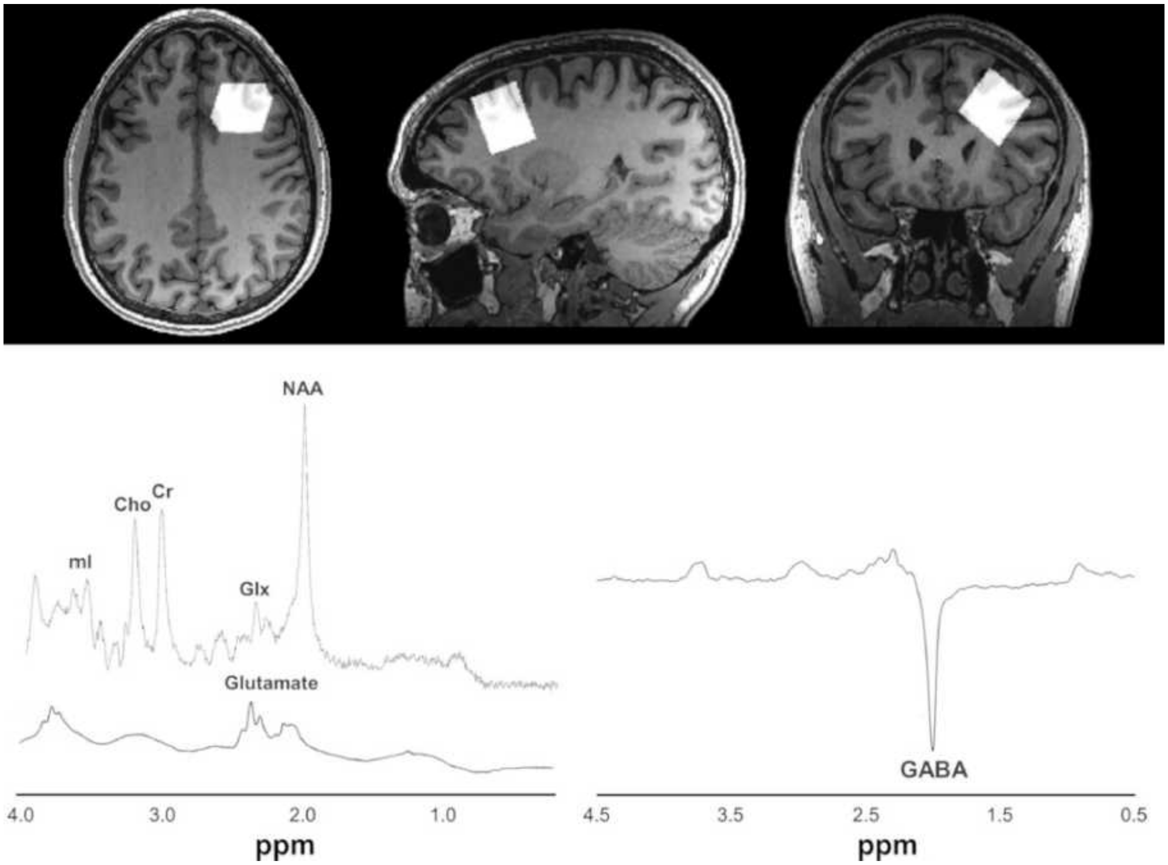

FIGURE 37–4. Sample proton magnetic resonance spectrum from the left dorsolateral prefrontal cortex. Spectra were obtained from a 15.6-mL volume of interest as shown on the magnetic resonance images. At higher field strengths, distinguishing glutamate from Glx is possible. Angulation of voxels to best accommodate anatomy is also possible. Cho, choline; CR, creatine/phosphocreatine; Glx, glutamate/glutamine; mI, myo-inositol; NAA, *N*-acetyl-aspartate; GABA, γ-aminobutyric acid. (Courtesy Frank P. MacMaster, Ph.D.)

MRI-based approaches are a viable tool in basic science studies. As a scientific method, it has served many purposes—mapping developmental trajectories, disease processes, and the effect of treatment. Thanks to its use of nonionizing radiation, MRI allows for repeated measures over time with a high degree of safety. MRI further avoids the physiologic changes inherent in the death process and the effects of the lag between death and fixation processing that are part of postmortem studies. Furthermore, for psychiatric diseases of childhood, like OCD and ADHD, there are virtually no postmortem studies. Hence, the investigation of psychiatric diseases in childhood has benefited from MRI approaches. It should be noted that MRI is obviously of lesser utility in children with braces or claustrophobia, in which case, alternative techniques mentioned above could be considered to measure the developing brain.

Other Functional Techniques. Electroencephalography (EEG) is one of the initial techniques widely used to study brain activity and is often used in studying pediatric neuropsychiatric groups. A standard EEG is a visual representation of the difference in voltage between two different cerebral locations using electrodes placed on the scalp. Essentially, EEG is a measure of the electrical activity generated by neurons. While it lacks the spatial resolution of an fMRI scan, it has excellent temporal resolution. Quantitative EEG can be used as a post hoc analysis approach to measure subtle differences in frequency changes and coherence of activity in brain regions. Recent advances allow for simultaneous recording of EEG and fMRI, thereby allowing for multimodal integration of brain function. Additional techniques to study brain function include the use of functional near-infrared spectroscopy (fNIRS) and magnetoencephalography (MEG). The use of fNIRS is growing in pediatric groups due to advantages such as higher tolerance to motion (compared to fMRI). Additionally, the device is portable, enabling its use both inside and outside of laboratory settings. The latter technique, MEG, relies on the magnetic field generated by electric activity in the brain. It is advantageous over other functional techniques, such as EEG, in identifying the focal point origin of epilepsy.

Critical Considerations

When acquiring and interpreting data from MR-based neuroimaging studies of children, a variety of factors merit consideration. A concise overview is presented below.

Technical Factors. With advances in computational techniques, there has been a shift from a priori hypothesis to the use of machine learning algorithms in exploring brain development. It allows the possibility to explore the relationship between several factors (e.g., between brain measures, behavioral measures, and environmental factors). However, the application of such advanced algorithms also requires large sample sizes. While current practices include sample sizes of ~25 participants, there is a growing emphasis to include sample sizes of more than 100 participants. In addition to enabling complex algorithms, large samples are necessary for replication of neuroimaging findings.

Additionally, MRI scanner strength has improved in the last decade, with humans being scanned at an ultra-high field strength of as high as 10.5T. However, there is limited research on such high field strengths in pediatric groups. Currently, most pediatric scans have been completed at 3T, with some studies performed at 7T. Adequate data supporting safety at ultra-high magnetic field strengths are required in pediatric groups. Finally, the capacity of children to remain quiet and still while being scanned is of particular concern to investigators using any imaging technique. Motion artifacts are problematic in studies as they can often render data of such poor quality as to make it unusable. Remaining still can be challenging even for healthy children, let alone those suffering from neuropsychiatric and neurodevelopmental disorders. Children are often naturally curious about the scanning environment. Some children can become quite anxious in the sometimes small, confined space of the magnet. Even with earplugs and headphones, the loud noises inherent in certain specific imaging sequences can be disturbing. Pharmacologic sedation has been used successfully in children who would be otherwise unable to tolerate neuroimaging in clinical settings, but in research studies, such procedures may entail unwanted side effects and alter the neurobiology being studied. For research studies, sedation and its potential risks are more ethically difficult to justify, especially in healthy control participants. Desensitization to the scanning environment with a “mock scanner” (Fig. 37–6) before the actual scan has been found to reduce subjective distress and heart rate, facilitating the successful completion of the study. Unfortunately, “mock scanners” can be costly and require considerable space in already crowded hospitals. Other means of desensitization, such as a careful description of the scanner, videos of its use, and attention to the questions of patients and their parents, may also be helpful in reducing anxiety and habituating children to the scanning environment to facilitate successful MR-based study (Table 37–1). Checking for motion is crucial for quality data analysis. Motion correction can be applied at the level of MRI acquisition using scanner-based tools. However, minor motion can be accounted for using post hoc motion correction techniques during data analysis.

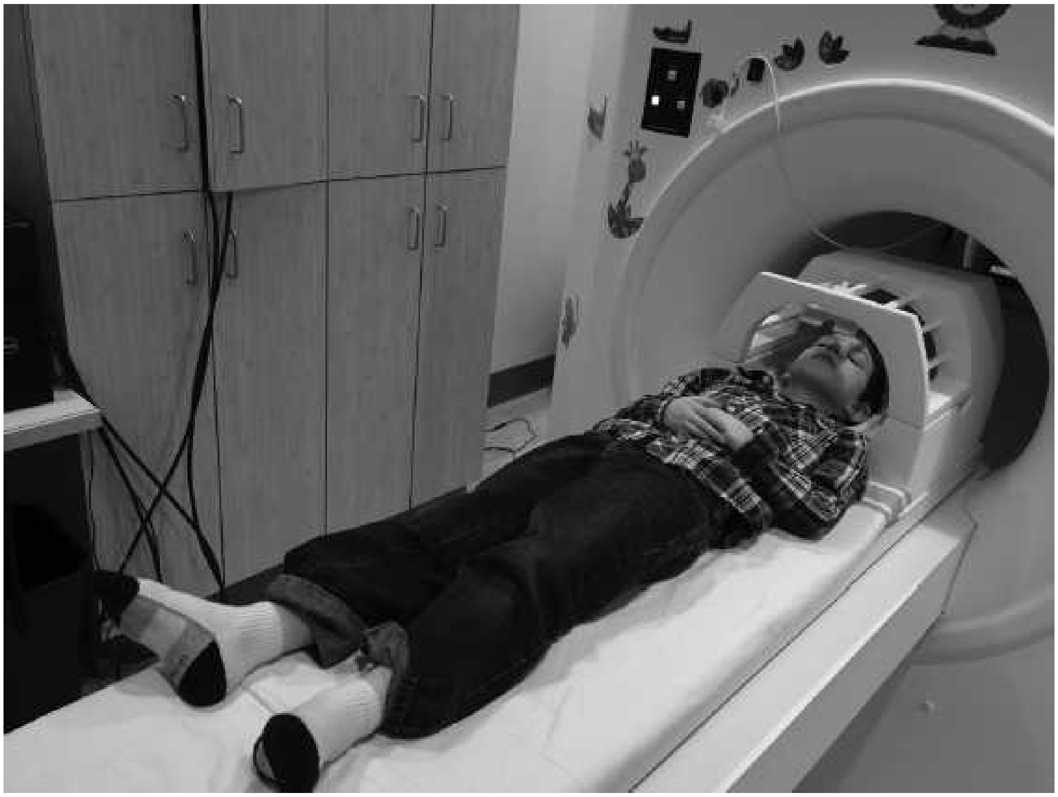

FIGURE 37–6. Child entering the mock scanner, which is designed to replicate the experience of a magnetic resonance scan, complete with the sounds that occur during the protocol to be used. (Courtesy Frank P. MacMaster, Ph.D.)

Neuroanatomical Factors. Smaller body size and brain maturation are key technical considerations in performing MR-based neuroimaging research in children. Children may not fit well into head coils designed for adults, leading to increased magnetic field inhomogeneity and decreased signal-to-noise ratios. Greater variability of the cardiorespiratory cycle in children may also contribute to increased physiologic noise during fMRI. Head motion, which is more common in children, can influence functional connectivity measures as well. However, the brain is surrounded by less bony and muscular tissue in children than in adults, so that MR surface head coils lie closer to the brain regions being imaged, possibly enhancing signal detection.

Table 37–1.
Recommendations for Scanning Young Pediatric Groups

Recommendation	Description
Prescanning training sessions	Provide links to audio, video, or online resources to MRI scanning. For instance, incorporating MRI scanning into a story (e.g., space flight) and having children practice with their parents has been found to increase compliance.
Mock scanner	Scheduling a visit to allow the child to get familiar with MRI scanning using a simulated environment can help reduce anxiety
Play therapy	On the day of scheduled visit, spending time with the child and playing short games to make the child comfortable helps reduce anxiety. Read the story again, and explain MRI scanning in simple terms (e.g., a camera that makes loud noises and takes pictures of the brain) Allow the child to take an MRI-safe toy (e.g., a teddy bear or a fidget toy) into the scanner
Parent in the MRI scanner room	Consider having a parent present in the MRI scanner room to help reduce anxiety. Parent should also be screened for MRI safety prior to entering the room.
Playing a movie	Have a list of children and youth movies that can be projected using an audiovisual device during MRI scan. This reduces the chances of children being bored and fidgeting during an MRI scan.
Giving breaks	Communicate that children can take breaks in between scans. Allow child to wiggle their toes or feet (without moving their head) between scans or allow a bathroom break at a halfway point during the scanning session. This provides flexibility and autonomy to a child during scanning.

	Talking to the child through the MRI microphone and providing a time frame for holding could help (e.g., this next set of pictures is about 5 minutes long, hold nice and still), although children do prefer to watch movies uninterrupted.
Providing incentives	At the end of the scanning session, children could be provided an incentive such as a toy or a certificate for completing their scan. For example, a group of researchers scanning children provided an astronaut certificate for their “space flight.”

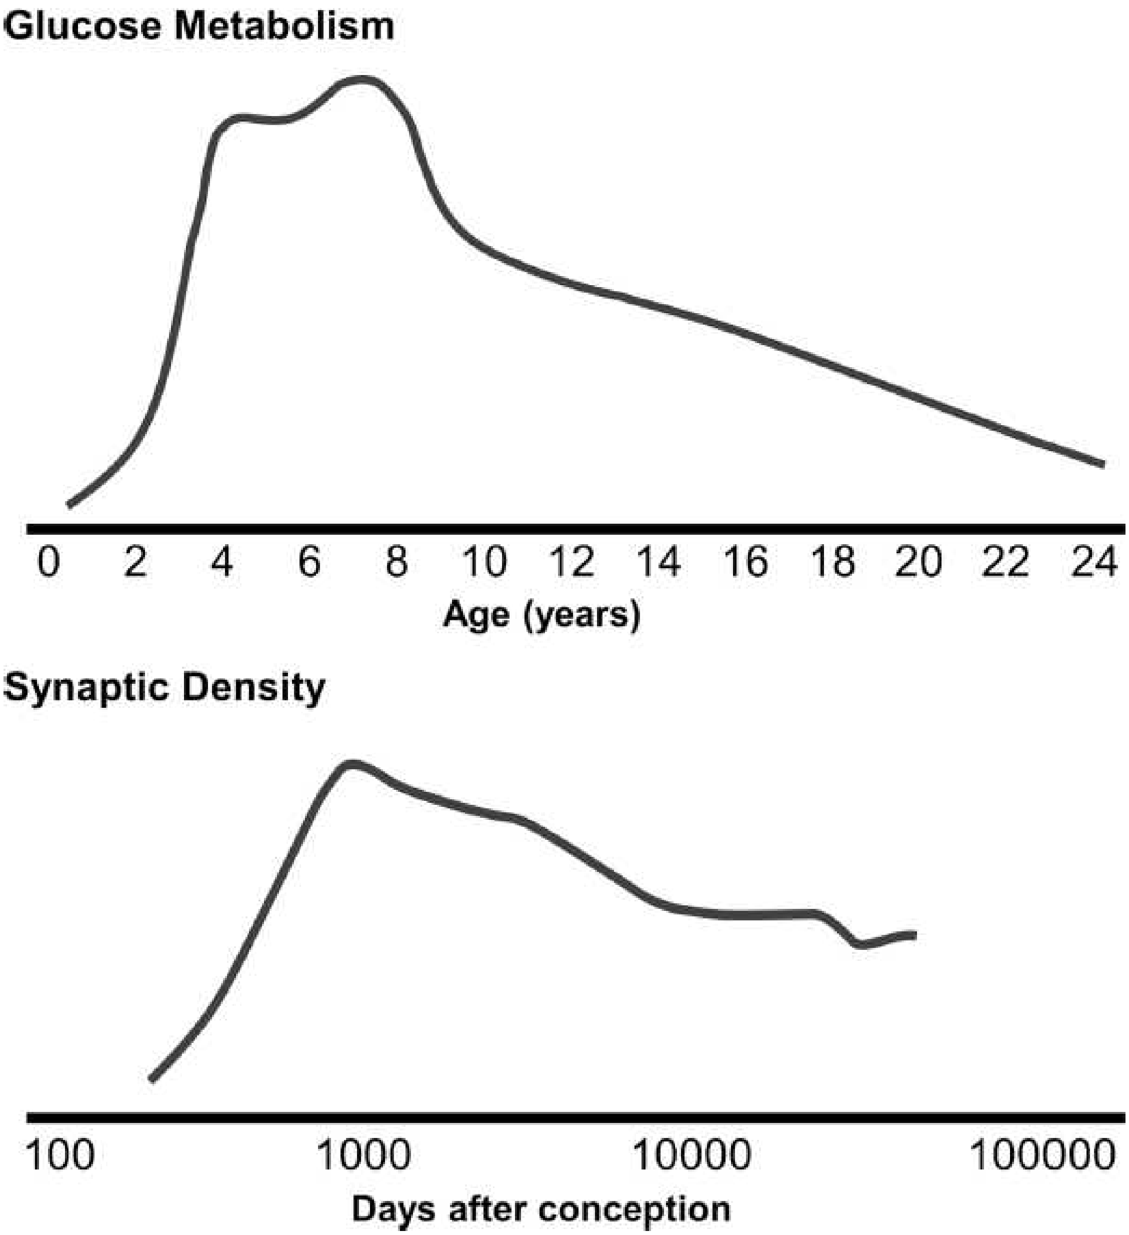

FIGURE 37–7. Schematic adapted from positron emission tomography studies of glucose metabolism (**top**) and synaptic density (**bottom**) as a function of age in children through young adulthood. Note the steep rise through childhood followed by a sharp decline just as puberty and adolescence begins. (Top, data from Chugani HT. Biological basis of emotions: brain systems and brain development. *Pediatrics.* 1998;102(5 Suppl E):1225–1229. Bottom, adapted from Rakic P, Bourgeois JP, Goldman-Rakic PS. Synaptic development of the cerebral cortex: implications for learning, memory, and mental illness. *Prog Brain Res.* 1994;102:227–243. doi:10.1016/S0079-6123(08)60543-9.)

Peak synaptic density within the brain occurs between 4 and 8 years of age (Fig. 37–7). This peak is associated with greater metabolic, and perfusion demands, which may lead to more robust increases in regional cerebral blood flow during neuronal activation and/or increased “noise” in fMRI experiments. Furthermore, the networking between brain regions is immature and may result in a weaker, more diffuse fMRI signal. Structurally, greater ratios of gray to white matter and less cerebrospinal fluid (CSF)—occupied free space around vasculature in children may lead to fundamental differences in the generation of MR signal in children versus adults. These factors must be accounted for when attempting to compare subjects of disparate ages.

The interpretation of fMRI signals in children is further complicated by structural differences because data processing typically involves the “warping” of study subjects’ brains to a standard brain atlas derived mainly from adults. The development of standardized brain atlases for children of different ages offers a solution to this methodologic problem. Still, brain volumes may vary during development even in same-aged children, so that the segmentation of brain into gray matter, white matter, and CSF may be necessary to generate individual descriptors of structural differences for use in statistical correction between study subjects. The use of study-specific templates for fMRI and voxel-based morphometry (VBM) is the most logical course. The volumetric MRI study of normal brain development in children and adolescents jointly sponsored by the National Institutes of Mental Health, Child and Human Development, and Neurologic Disorders and Stroke has recently been initiated and will generate a large normative database specific to pediatric structural maturation. Given the aforementioned variation in the developing brain and its effect on analysis methods, the importance of this resource cannot be overestimated.

Cognitive Factors. Another possible confound in the interpretation of certain fMRI paradigms in children relates to their ability to perform the cognitive tasks under investigation. Across development, children vary considerably in cognitive skill and their capacity to sustain attention and remain “on task.” Potential tasks need to be vetted thoroughly in children and adolescents before robust interpretations of functional data can be made. Cognitive-based fMRI studies comparing children and adults should account for accuracy and reaction time to avoid falsely attributing performance differences to underlying neurobiology. Assessment of effort should also be considered because some children may guess or give up when a cognitive task is too difficult or too boring. In designing a cognitive paradigm for use in an fMRI study of children, tailoring the level of task difficulty to individual capability may help to ensure consistent performance across subjects at different developmental stages. The possibility that children may use different cognitive strategies on a given task can be examined by correlating task performance with neuropsychological measures. The correlation of activation patterns with performance rather than age may help to identify true functional differences based on brain maturity rather than structural- or performance-based differences, which can vary with age and between same-aged subjects during development.

Functional neuroimaging studies of executive functions, including working memory (the ability to respond to new situations on the basis of stored information) and neurobehavioral response inhibition (inhibition of context-inappropriate responses), have demonstrated similar regional activation patterns (e.g., prefrontal cortex [PFC]) in children and adults, with children recruiting larger volumes of activation with greater signal intensity. This suggests a less specific neural network and/or less efficient processing of cognitive stimuli in childhood. Not only may children display different activation strengths in response to stimuli, they may also show regional differences as well. On a task of spatial working memory, adults activated the anterior cingulate, a structure critically involved in arousal and mediating response conflict, whereas children did not. Lower accuracy on the task among children may be related to an incompletely developed anterior cingulate, resulting in a relatively reduced ability to modulate competing responses. In general, the functional connectivity between the anterior cingulate and other cortical and subcortical structures appears to increase with age, as demonstrated in a ^{1}H-MRS study in humans.

Opposite laterality of activation may also distinguish healthy children from healthy adults on tasks of response inhibition and working memory. Children may also recruit subcortical (e.g., basal ganglia, thalamus) and limbic (e.g., amygdala, hippocampus) structures to support incompletely developed PFC in mediating response inhibition. Moreover, whereas both healthy children and adults show altered activation of the amygdala in response to fearful faces as measured by fMRI, children but not adults show activation for neutral faces, as well as fearful faces, further suggesting that more specific neural processing of information develops with age.

Clinical Factors. Recent research has highlighted variations in symptom manifestation of neuropsychiatric conditions in pediatric groups compared to adults. For example, inattention (a common symptom across many neuropsychiatric conditions) may manifest differently in children versus adults. There is a growing emphasis on integrating information at various levels (i.e., from genes to behavior) to better understand differences/similarities in the presentation of mental disorders. This serves as the guiding principle for the Research Domain Criteria (RDoC) Initiative launched by the National Institute of Mental Health (NIMH). The RDoC framework includes three basic assumptions. First, RDoC conceptualizes that psychiatric illness can be addressed as disorders of brain circuits. This is akin to lesions in neurologic conditions such as stroke. However, a brain region does not operate in isolation. The first RDoC assumption thus accounts for the dependencies between different brain regions that serve an underlying behavior (e.g., the role of the cortico-striato-thalamo-cortical circuit instead of just the caudate in ADHD), Second, it assumes that dysfunction in the brain circuits can be identified using clinical neuroscience tools (MRI, fMRI, EEG, etc.). Finally, RDoC assumes that integrating data across scientific fields (e.g., genetic and clinical neuroscience) will help in identifying biosignatures which will support clinical symptoms and management. This allows for a transdiagnostic approach in mental health. For example, the manifestation of reward processing could be studied across mood disorders, addiction, and psychosis to identify underlying genetics, brain structure or function, fear response, and determine appropriate treatment. This will aid in the development of precise and individualistic treatment based on clinical symptom manifestation and the underlying neurobiology, instead of relying on more generic diagnostic labels.

NORMAL DEVELOPMENT

Childhood and adolescence are times of great change and vulnerability. As most psychiatric disorders begin during this period, they can only be understood in the context of brain development. Brain size increases considerably in utero through 2 years of age, during which time synaptogenesis is most active. While total brain volume is comparatively static after 5 years of age, there are two dynamic processes that are ongoing through adolescence into young adulthood—synaptic pruning and myelination. Evidence suggests that increased myelination, connectivity, and changing functional activation patterns indicate that more efficient/specialized connections between brain regions are being made from childhood through adulthood.

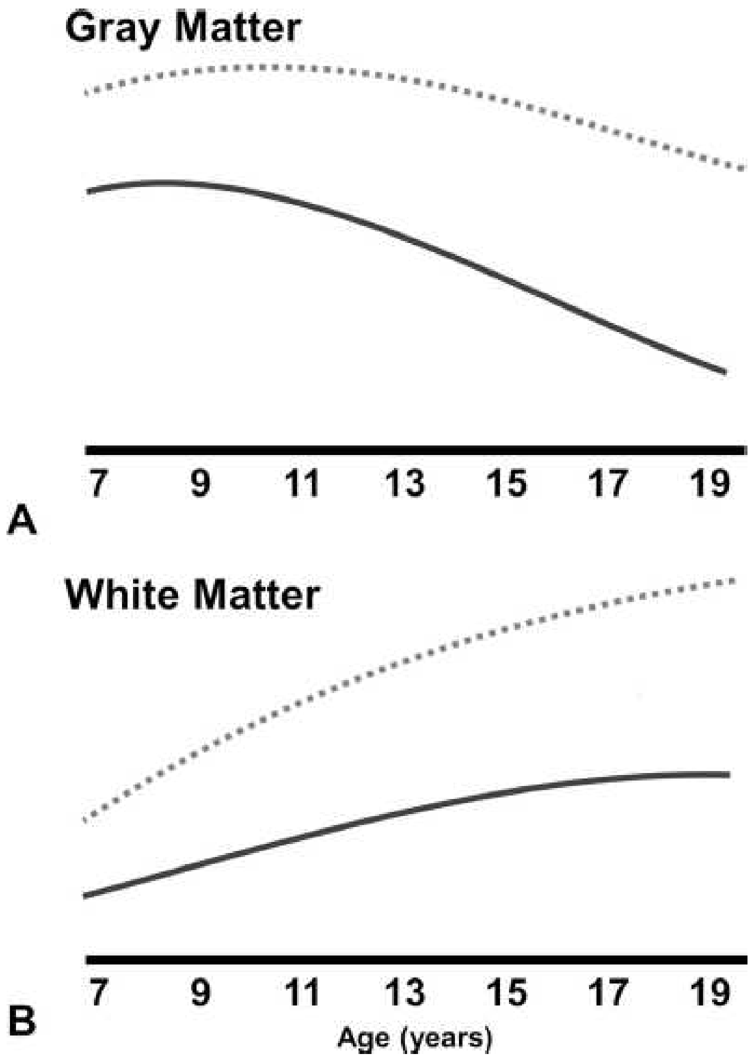

FIGURE 37–8. Schematic showing growth and aging changes in gray and white matter from childhood through adolescence. **A:** Gray matter volume reached a maximum by 9.5 years of age in females (*solid line*) and 10.5 years of age in males (*broken line*) and thereafter declined linearly. This is most pronounced in the frontal and temporal lobes. **B:** White matter volume increased rapidly until 12 to 15 years of age then slowed to eventually plateau. (Adapted from Giedd JN, Raznahan A, Alexander-Bloch A. Child psychiatry branch of the National Institute of Mental Health longitudinal structural magnetic resonance imaging study of human brain development. *Neuropsychopharmacology.* 2015;40(1):43–49. doi:10.1038/npp.2014.236, with permission from Springer Nature.)

Gray Matter

Gray matter volumes peak in midchildhood to early adolescence, earlier in females than males. They then plateau briefly and show a decrease following puberty (Fig. 37–8A). This pattern of gray matter maturation parallels changes in local cerebral metabolic rates for glucose in the cerebral cortex as a function of age (Fig. 37–7). These developmental changes most likely represent an increase in the efficiency of neural processing via the pruning of excessive synaptic connections. It is not clear which cellular changes (i.e., loss of neurons, dendrites, axons, and/or neuropil) are responsible for the reduction of gray matter. The relationship between metrics of brain morphology and age is so strong that cortical thickness, as measured using MRI, can accurately predict an individual's age during childhood and adolescence. When considering the developmental basis of normal and abnormal cognitive/emotional function, it is important to note that it is heterochronous. That means that the timing, degree, and rate of cortical and subcortical gray matter change appear to be regionally specific.

White Matter

The volume of white matter increases roughly linearly in the brain during childhood and adolescence. This is consistent with myelinization during this time (Fig. 37–8B). Growth in cortical white matter appears to be regionally specific. The most dramatic increase in white matter occurs in the dorsolateral PFC (DLPFC) between 5 and 17 years of age. Consistent with the progressive development of executive function through adolescence and into early adulthood, a segmentation analysis of MRI data found that gray matter reduction in the frontal cortex continued into young adulthood after gray matter volumes had stabilized in other cortical regions. The "reduction" of frontal lobe gray matter was thus hypothesized to reflect the effects of an increase in myelination (and hence the relative amount of white matter). This interpretation is supported by the inverse relationship between cortical gray matter and brain growth—presumably due to white matter increase—in the frontal lobes. It has been suggested that myelinization may be as important to brain maturation as synaptic pruning. Indeed, the capacity for attention—a function largely attributable to the frontal lobe—has been shown to increase with larger areas of the anterior cingulate cortex over development, possibly the result of increased myelination. The corpus callosum (CC)—the white matter tract connecting the hemispheres—demonstrates a particularly dynamic growth pattern (Fig. 37–9). Unlike the posterior–anterior progression of brain development described in much of the preclinical literature, CC growth occurs in a rostrocaudal wave between 3 and 15 years of age (see

Fig. 37–9). It may be that CC growth parallels synaptogenesis in associated cortical regions rather than pruning and myelinization. In a large study of 103 healthy participants (5 to 32 years of age), nonlinear development of major white matter pathways was observed. There were significant within-subject changes in the majority of children and early adolescents, with these changes being completed by late adolescence for projection and commissural tracts. In contrast, association tracts demonstrated postadolescent within-subject maturation of both fractional anisotropy and mean diffusivity.

Biologic Sex Differences

Biologic sex also plays a significant role in brain development. In a large longitudinal MRI study of cortical volumes in 145 healthy children and adolescents (4 to 20 years of age), gray matter volume was found to peak and then decline after puberty in the parietal, frontal, and temporal lobes but on different time scales (Table 37–2). In contrast, gray matter in the occipital cortex increased through early adulthood (approximately 20 years of age). With regard to biologic sex differences, the peak for gray matter volume in the frontal and parietal lobes occurs nearly 1 year earlier in girls than boys. This seems to coincide with sex-specific differences in the timing of puberty and suggests the possible influence of gonadal hormones on brain development.

Sex-specific and age-related differences in gray matter volumes have also been noted in the basal ganglia, hippocampus, and amygdala (Table 37–3). Although reduction of basal ganglia volumes has been demonstrated in both sexes through young adulthood, gray matter loss in this region is most dramatic in boys, especially in the caudate between the ages of 6 to 12 years. It is possible that this maturational difference is related to the preponderance of basal ganglia–associated psychiatric disease (e.g., OCD and ADHD) in boys during this critical developmental window. In contrast to the basal ganglia and some areas of the cerebral cortex, the volume of the amygdala and hippocampus increases with age. Volumetric and functional abnormalities of these regions have been associated with depression and anxiety disorders, known to occur more commonly in females, particularly after the onset of puberty. The relatively smaller amygdala and larger hippocampal volumes that emerge in girls than in boys around the time of puberty may be particularly relevant in this regard. The preponderance of estrogen receptors in the amygdala and androgen receptors in the hippocampus suggests that gonadal hormones may influence age-specific changes in these regions and possibly the emergence of mood and anxiety disorders in adolescent girls. The pituitary gland also demonstrates a striking sex difference, with females developing a larger pituitary gland than males, particularly during adolescence. This may be associated with the differential timing of puberty in males and females.

SPECIFIC NEUROPSYCHIATRIC DISORDERS

Attention-Deficit/Hyperactivity Disorder

The phenomenology, nosology, and empirically based treatment for ADHD have been well delineated. This makes pediatric ADHD a prime candidate for neurobiologic studies of development. ADHD is also relatively consistent in expression across the lifespan. Therefore, the results of studies of the disorder in children, closer to illness onset, are applicable to adult subjects. Various neuroimaging strategies, including PET, fMRI, volumetric/anatomic MRI, and ^{1}H-MRS, have been used to better elucidate the pathogenesis and mechanisms of treatment response in ADHD.

Table 37–2.
Peak Cortical Gray Matter Volumes by Age and Sex

Cortical Region	Girls (Age in Years)	Boys (Age in Years)
Parietal	10.2	11.8
Frontal	11.0	12.1
Temporal	16.7	16.5

Data from Giedd JN, Raznahan A, Alexander-Bloch A, Schmitt E, Gogtay N, Rapoport JL. Child psychiatry branch of the National Institute of Mental Health longitudinal structural magnetic resonance imaging study of human brain development. *Neuropsychopharmacology.* 2015;40(1):43–49.

Prefrontal Cortex. Core deficits in attention, arousal, and impulse control characterize children with ADHD. The PFC modulates these functions and is the seat of “executive” control. It is not surprising that the PFC has been implicated in the pathophysiology of ADHD. Smaller prefrontal cortical volumes, particularly of the superior and inferior frontal gyri, have been consistently noted in volumetric MRI studies of children with ADHD. However, one study found girls with ADHD to have normal frontal lobe volumes; this finding may be related to the lower prevalence of ADHD in females than males and an underlying sex difference in the pathophysiology of the disorder. Lower global cerebral metabolism in girls with pediatric ADHD than in male patients and normal controls has been noted, further suggesting sex-specific differences in the neurobiology of ADHD. Smaller PFC volumes correlate with impaired response inhibition in children with ADHD. A large-scale study of children with ADHD found that the structural maturation of the PFC lags behind typically developing children by 2 to 3 years. When considering the potential behavioral ramifications of such a lag in development, the implications for the symptoms of ADHD are clear. In addition, using phosphorus magnetic resonance spectroscopy (^{31}P-MRS), lower levels of membrane phospholipid (MPL) precursors were observed in older ADHD children as compared to healthy children. Lower MPL precursor levels suggest a possible underdevelopment of neuronal processes and synapses in ADHD. It was suggested that bottom-up developmental dysfunction, starting in the basal ganglia, might result in ADHD (Fig. 37–10). During a response conflict task that typically involves the anterior cingulate in normal subjects, adult patients with ADHD failed to demonstrate a significant anterior cingulate response. Of interest, both increased and decreased PFC activation during response inhibition have been found in different studies. These discrepant findings may be accounted for by the inverse relationship noted between symptom severity and perfusion in children with ADHD. Specifically, perfusion-based functional neuroimaging studies of "sicker" patients would start from a lower baseline than studies of less symptomatic patients. This may result in a reduction in signal when the PFC is involved.

Table 37–3.
Sex Differences in Brain Volumes

Region	Gender Difference (Age in Years)
Total brain volume	10% larger in boys (4–18)
Cerebellum	8% larger in boys (4–18)
Caudate and putamen	More dramatic decrease in boys (preadolescent)
Amygdala	Larger in girls (postadolescent)
Hippocampus	Larger in boys (postadolescent)

Basal Ganglia. Another aspect of the frontal–striatal loop, the basal ganglia, has been repeatedly demonstrated to be abnormal (with regard to volumes and reversed asymmetry) in pediatric ADHD. The deficits in response inhibition and attention noted in children with ADHD have also been associated with smaller volumes and lower activation of the right and left caudate. The basal ganglia have been implicated in ADHD, TS, and OCD, and may account for the high degree of comorbidity among these conditions. ^{1}H-MRS studies have noted lower levels of the putative neuronal marker NAA and greater levels of Cho, a critical membrane component, in the striatum bilaterally in pediatric ADHD patients. More recently, ^{1}H-MRS studies of pediatric ADHD patients identified greater frontal–striatal Glx levels in medication-free pediatric patients with ADHD 7 to 16 years of age as compared to age- and sex-matched controls. Lower NAA levels suggestive of reduced neuronal viability may result from excess activity of Glx neurons, which can be toxic. Moreover, ADHD children also show reduced striatal GABA. Given evidence that changes in Cho, NAA, Glx, and GABA may be reversible in other neuropsychiatric conditions, longitudinal ^{1}H-MRS studies of these metabolites in ADHD are critical. As mentioned above, ADHD patients have lower PFC and basal ganglia MPL precursor levels than healthy children. In the basal ganglia, these deficits appear earlier, possibly indicating a bottom-up change in developmental trajectory. No significant differences were noted in the superior temporal region.

Cerebellum and Other Regions. Structural neuroimaging studies have demonstrated smaller cerebellar volumes in girls and boys with ADHD. This smaller volume may be localized to the vermis, a brain region involved in maintaining attention. In an fMRI study of motor function in pediatric ADHD patients, greater impairment in task performance was associated with lower cerebellar activation. Furthermore, motor impairment in ADHD patients was also associated with lower temporal lobe activation but greater thalamic activation. Moreover, a large-scale study showed that the temporal pole and fusiform gyrus are also significantly thinner in ADHD children compared to controls. This suggests that complex network-wide dysfunctions might underlie the symptoms of ADHD. This hypothesis is supported by the findings of smaller anterior and poster aspects of the CC in ADHD patients.

Medication Effects on Brain Function in ADHD. Methylphenidate (MPH) is the first-line treatment for ADHD. Studies found that MPH changes frontal–striatal activation in pediatric patients with ADHD, with greater PFC and striatal activation as measured by fMRI demonstrated in

ADHD patients. In addition, MPH was found to improve ADHD patient performance on the response inhibition task. Predrug activation during the task was greater among patients than with controls, suggesting that frontal cortical hyperactivity in ADHD may play a compensatory role that is further enhanced by MPH. In the striatum, predrug activation was lower in pediatric patients with ADHD than in pediatric controls. This deficit appeared to be corrected by MPH. MPH-treated healthy children also improved in their ability to inhibit inappropriate response. However, improved performance in healthy children was associated with a distinct pattern of frontal–striatal activation. Aligned with this, another study showed that MPH normalized fronto-striato-thalamo-parietal dysfunction and upregulated ventral fronto-temporal regions in adolescents with ADHD during a sustained attention task. These differences in MPH-related activation could reflect a fundamental abnormality of frontal–striatal dopamine systems in patients with pediatric ADHD as compared to healthy children. Positive correlation between ADHD symptom severity and increased midbrain accumulation of ^{18}F-dihydroxyphenylalanine (^{18}F-DOPA), a marker of dopamine synthesis, lends further support to the role of dysfunctional dopamine systems in ADHD. There are data suggesting a developmental shift in dysfunction of dopamine from the midbrain in childhood and adolescence to frontal cortex during adulthood in ADHD. Interestingly in children with ADHD, responders to MPH have greater gray matter concentrations compared to nonresponders in the caudate. This is similar to a larger posterior hippocampus predicting better response to antidepressants in adults with depression. The predictive power of imaging for treatment response has yet to be fully explored in child and adolescent psychiatry.

A recent meta-analysis of fMRI studies of the effect of stimulants on brain function in ADHD examined 14 data sets with 212 children with ADHD. Stimulants consistently enhanced right inferior frontal cortex and insula activation, with a smaller effect on putamen activation. This change in activation was present in those receiving MPH alone. The inferior frontal cortex and insula play a role in cognitive control and an increase in activation may represent the positive clinical response found with treatment.

Depressive Disorders and Bipolar and Related Disorders

Biologic studies of depressive disorders and bipolar and related disorders are providing increasingly converging evidence that alterations in medial temporal (e.g., amygdala, hippocampus) and prefrontal–striatal circuits may be involved in the symptomatology of patients with MDD and BP-I (Fig. 37–11). Although the literature is not entirely consistent, it appears that lesions to the left hemisphere are more associated with depression, whereas right-sided lesions tend to be more associated with mania.

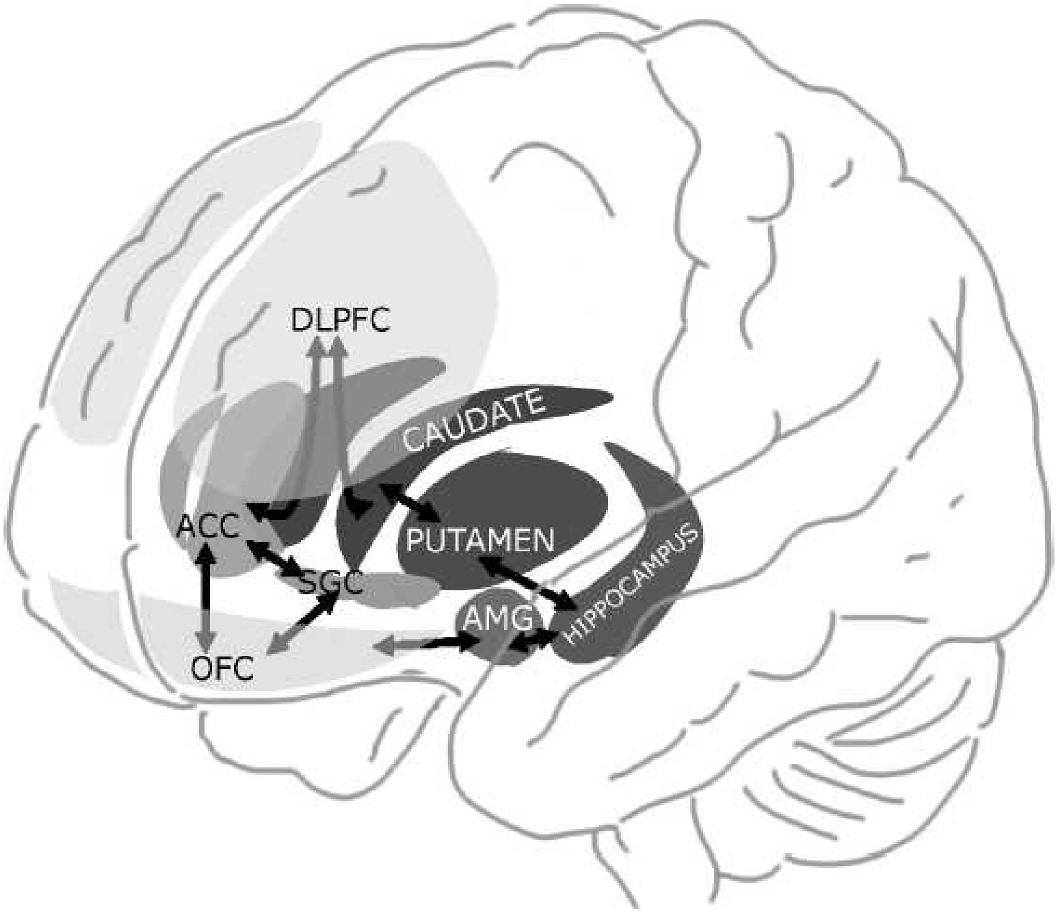

FIGURE 37–11. Brain regions implicated in the pathophysiology of major depressive disorder. ACC, anterior cingulate cortex, AMG, amygdala, DLPFC, dorsolateral prefrontal cortex, SGC, subgenual cingulate cortex. (Courtesy Sneha Chenji, PhD.)

Frontal Lobe and Striatum. In adults and adolescents with MDD, smaller overall frontal lobe volumes have been among the more consistent findings in structural neuroimaging studies. In addition, adolescents with MDD were found to have significantly smaller frontal white matter volumes but larger frontal gray matter volumes than healthy comparison adolescents, even after controlling for age and whole brain.

Cortical thickness in the middle frontal gyrus bilaterally and the left caudal anterior cingulate was found to be greater in adolescents with MDD as compared to healthy control participants. Replicating and extending this finding in adults, thicker caudal anterior cingulate was also found with first-episode MDD. Left middle frontal gyrus was inversely correlated with age in MDD subjects. This may indicate an altered developmental path in youth with MDD. MRI and PET investigation in adults with MDD and BP-I have reported strikingly localized, left-sided smaller volume in the subgenual region of the prefrontal cortex (SGPFC). This smaller SGPFC was associated with lesser cerebral blood flow. These effects were most prominent in MDD and BP-I patients who had at least one first-degree relative with MDD or BP-I (familial MDD or BP-I). In patients with MDD or BP-I without family history of MDD or BP-I (nonfamilial MDD or BP-I), no significant differences were observed in the left or right SGPFC. In an additional sample, a smaller left SGPFC volume was also noted in 30 young women with early-onset MDD (18 to 23 years of age) and 18 middle-aged women with recurrent MDD (24 to 52 years of age) than in age-matched controls (19% difference).

A study of 22 psychotropic-naive pediatric patients with MDD (9 to 17 years) compared to 22 case-matched controls found that patients with nonfamilial MDD had significantly larger left-sided but not right-sided prefrontal cortical volumes than patients with familial MDD and controls. In both the familial and nonfamilial pediatric MDD subgroups, left prefrontal volumetric abnormalities remained significant after controlling for severity of anxiety. This suggests that this region is integral to the pathogenesis of depression in children. Reduced left-sided prefrontal cortical volume was associated with increased severity of depression in familial but not nonfamilial patients with MDD. Longer illness duration also tended to be associated with reduced left prefrontal cortical volume in familial but not nonfamilial MDD patients. These results, coupled with investigations in adults, suggest that left-sided prefrontal cortical volume reduction in familial MDD patients may reflect degeneration of left prefrontal cortical volume, whereas increased left prefrontal cortical volume in psychotropic-naive pediatric patients with nonfamilial MDD may reflect alteration in the developmental maturation of the PFC.

Left PFC has been further implicated in pediatric MDD in two recent ^{1}H-MRS investigations. Increased left orbitofrontal Cho levels were observed in 22 depressed adolescents as compared to 43 control adolescents.

Increased orbital frontal Cho levels were most prominent in adolescent patients with familial MDD as compared to both nonfamilial MDD patients and controls (Dr. Perry Renshaw, personal communication). Increased left but not right DLPFC Cho concentrations were also observed in treatment-naive pediatric patients with MDD as compared to age- and sex-matched controls. Increased Cho concentrations in pediatric MDD patients versus controls persisted even after controlling for severity of anxiety. Mean left dorsolateral prefrontal cortical (DLPFC) Cho concentrations were increased in familial MDD patients as compared to both nonfamilial MDD patients and healthy pediatric controls. Lower Cho concentrations were also observed in the right anterior cingulate. Alterations in Cho as measured by ^{1}H-MRS have been hypothesized to result from abnormalities in signal transduction involving phosphatidylcholine second messenger cascades and could reflect changes in glucose metabolic rates and/or neuroendocrine function. Increased left prefrontal Cho levels may also be consistent with functional neuroimaging studies demonstrating reduced prefrontal cortical metabolism in adults with MDD. Functional neuroimaging studies have demonstrated that reduced prefrontal cortical activation in depressed adolescents and adults normalizes following treatment-induced symptom remission. Because Cho alterations in adult patients with MDD appear to be reversible with treatment, the Cho resonance may represent a potential target for treatment intervention in pediatric MDD, warranting longitudinal ^{1}H-MRS investigations in these patients. Finally, consistent with findings in adult patients with MDD, lower anterior cingulate Glx concentrations have been noted in pediatric MDD patients than in healthy controls. Glx was also associated with severity of illness in the MDD patients. In addition, distinct differences were noted in familial versus nonfamilial MDD patients. Subsequent investigation, using a more robust spectral fitting method, found that the lower anterior cingulate Glx in patients was due to glutamate but not glutamine. In 20 medication-free youth with MDD, lower anterior cingulate GABA was observed as compared to controls, with this difference being more pronounced in those with anhedonia. Recently, a small case series in adolescents with MDD replicated a finding in adults with MDD that showed an increase in DLPFC glutamate in response to repetitive transcranial magnetic stimulation treatment.

In contrast, recent ^{1}H-MRS investigation in 10 medication-free children with BP-I versus 10 healthy children found increased glutamate and glutamine (Glx) levels bilaterally in the frontal lobes and basal ganglia in children with BP-I. Cho levels did not differ in frontal lobes or basal ganglia in patients with BP-I or controls. Increased lipid levels were also found bilaterally in the frontal lobes of children with BP-I. In contrast, ^{1}H-MRS investigation of anterior cingulate cortex in pediatric patients with BP-I versus healthy pediatric controls found no significant differences in Cho, Glx, GABA, or the neuronal marker NAA. Consistent with findings in adults, effective lithium treatment was, however, associated with a reduction of the ^{1}H-MRS neurochemical marker myo-inositol in the anterior cingulate cortex of children with BP-I. A recent VBM study found that subjects with BP-I had reduced gray matter volume in the left DLPFC as compared to healthy controls.

In concert with the frontal lobe, the striatum plays an important role in executive and emotional processing. Evidence from adult imaging studies implicates the striatum in the pathophysiology of depressive disorders. A recent study noted that patients with MDD had significantly smaller right striatum (2.3% smaller) and caudate volumes (3.9% smaller) than healthy subjects. Furthermore, right striatum volumes were inversely correlated with increased severity of depression. Moreover, increased functional connectivity between the left DLPFC and the striatum in depressed adults is associated with better treatment response to noninvasive brain stimulation therapy. These findings provide fresh evidence for abnormalities in the striatum of pediatric MDD and bolster the hypothesis of dysfunction in the cortico-limbic–striatal–pallidal–thalamic circuit in the pathophysiology of MDD and serve as a foundation for the development of better treatment approaches for pediatric MDD patients.

Amygdala, Hippocampus, and Pituitary. Although prefrontal cortical involvement in pediatric MDD may be specific to the depressive state, abnormalities of the amygdala in depressed children and adolescents may be more associated with the severity of anxiety than with the severity of depression. Ratios of left and right amygdala to the hippocampal volume were found to be significantly larger in treatment-naive pediatric patients with MDD than in 23 age- and sex-matched controls. Furthermore, ratios of amygdala to hippocampal volume in pediatric patients with MDD were positively correlated with the severity of anxiety but not with the severity of depression or duration of depressive illness. Amygdala volumes were larger bilaterally in patients with MDD than in controls. In a magnetic resonance spectroscopic imaging ^{1}H-(MRSI) study of the amygdala in adolescents with depression, lower choline-to-creatine (Cho-to-Cr) ratios were noted in the left, but not right, amygdala in patients than in controls. This change in cytosolic choline may be secondary to corticosteroid-neuroendocrine–driven changes, given that increases in cortisol can result in lower Cho concentrations. Right and left hippocampal volumes were smaller in MDD patients. Not only are comorbid anxiety symptoms and disorders extremely common in patients with MDD but also excessive fearfulness in adolescence has been found to predict the development of MDD in early adulthood. Smaller left hippocampal volumes have been noted in pediatric patients with MDD with a familial history of depression than in controls. It may be that patients with a family history of depression are driving the smaller hippocampal volumes noted in previous reports. Smaller right hippocampal volumes have been found in youth with MDD with a normal body mass index (BMI) compared to MDD youth with high BMI and healthy controls. However, smaller left hippocampal volumes were inversely related to increased BMI in the high BMI MDD group. Therefore, variabilities in factors such as familial history and BMI should always be considered. In a closer examination of the hippocampus using ^{1}H-MRSI, reduced left, but not right, NAA concentration was noted in MDD patients and those with treatment-resistant MDD (i.e., unresponsive to at least two medications) as compared to age- and sex-matched controls. This indicates that neuronal viability may be reduced in pediatric MDD.

In adolescents and adults with MDD, at rest, the amygdala shows abnormal connectivity with the hippocampus, parahippocampal gyrus, insula, caudate, and brain stem. Abnormal connections in adolescents with MDD were more prominent in the cognitive control network and default mode network. Much of this connectivity has been inversely correlated with depressive symptoms. Use of emotional facial expressions as fMRI stimuli is common as a probe of affective processing in the amygdala in adults and children. An fMRI study of amygdala response to fearful faces in children with generalized anxiety disorder (GAD) and panic disorder compared to children with MDD and healthy pediatric controls demonstrated altered activation of the amygdala in both patients with MDD and patients with GAD/panic disorder, with the magnitude of signal change in amygdala activation being most associated with the severity of the child’s rating of everyday anxiety. This increase in amygdala arousal to negative stimuli was recently replicated in 32 adolescents with MDD and 23 age- and gender-matched controls.

It should be noted that greater amygdala volume is one of the more consistent findings in adults with BP-I. fMRI studies in adults with BP-I have also demonstrated increased amygdala activation in response to fearful facial affect. More recently, an event-related fMRI study reported that pediatric patients with BP-I demonstrated reduced memory for emotional faces and had increased neural activation in the striatum and anterior cingulate cortex when successfully encoding happy faces, and in the orbitofrontal cortex when successfully encoding angry faces. There were no between-group differences in neural activation during fearful face encoding. Consistent with adult BP-I studies, multiple fMRI studies reported increased amygdala activation in response to fearful faces. Differences across studies of BP-I may have to do with differences in disease state. Longitudinal MRI studies of amygdala volume and function in pediatric patients with MDD are clearly warranted to determine whether increased amygdala volume and altered activation level may serve as potential biomarkers for BP-I.

More recently, larger pituitary gland volumes were noted in adolescents with MDD than in case-matched controls. This was replicated in an independent treatment-naive sample. In the second sample, it was noted that the difference in volume appeared to be driven by nonfamilial MDD patients. Of interest, depressed patients with BP-I demonstrated larger pituitary gland volumes than controls. This was not consistent with a published adult study of BP-I and a pediatric sample. The main difference between these reports is the disease state (depressed vs. mainly euthymic). This reinforces the need for studies of BP-I across the illness course and the need for further studies to differentiate MDD from BP-I.

Obsessive-Compulsive Disorder

There is a growing literature pointing to a dysfunction in ventral prefrontal–striatal–thalamic and medial temporal circuitry in OCD (Fig. 37–12). The phenomenology, nosology, and empirical treatment for childhood OCD have been well established, rendering it an ideal candidate for developmental neurobiologic study. In comparison to depressive and bipolar and related disorders, OCD is more consistent in its expression across the lifespan. This allows investigators to study the illness close to onset, with the results remaining applicable to adult subjects. Studies in pediatric OCD have focused on treatment-naive populations. This minimizes potential confounds such as illness duration and medication exposure. As described in the following sections, evidence is converging that suggests a pharmacologically reversible, Glx-mediated thalamic–cortical–striatal dysfunction in pediatric OCD that may serve as a reliable pathophysiologic and treatment response marker for the illness (Fig. 37–13).

Basal Ganglia. Volumetric neuroimaging studies in pediatric patients with OCD have demonstrated smaller basal ganglia volumes in patients that were associated with OCD symptom severity but not illness duration. In addition, smaller globus pallidus volumes were also noted in treatment-naive pediatric OCD patients than in controls. Recently, however, 26 adolescents with OCD showed greater gray matter volume in the bilateral caudate as compared to healthy controls (*N* = 26). This may reflect fundamental differences in what properties are measured using VBM as compared to the manual tracing technique. It was recently shown, in 29 adolescents with OCD, that those who responded to an allocated treatment (selective serotonin reuptake inhibitor [SSRIs] or cognitive behavioral therapy [CBT]) had larger caudate volumes than nonresponders and healthy controls. In another study, greater caudate Glx concentrations, as measured by ^{1}H-MRS, were also observed in treatment-naive pediatric OCD patients than in age- and sex-matched healthy pediatric controls (Figs. 37–14 and 37–15). No significant differences in Glx concentrations were observed between OCD patients and controls in the occipital cortex, a region not implicated in the pathogenesis of OCD. After 12 weeks of treatment with the SSRI, paroxetine, but not with CBT, caudate Glx concentrations in OCD patients decreased to levels that did not differ significantly from those in controls (Fig. 37–16). Greater pretreatment caudate Glx concentrations predicted a more robust response to paroxetine in OCD patients. More recent investigation suggested that caudate Glx concentrations may persist even after medication discontinuation in pediatric OCD.

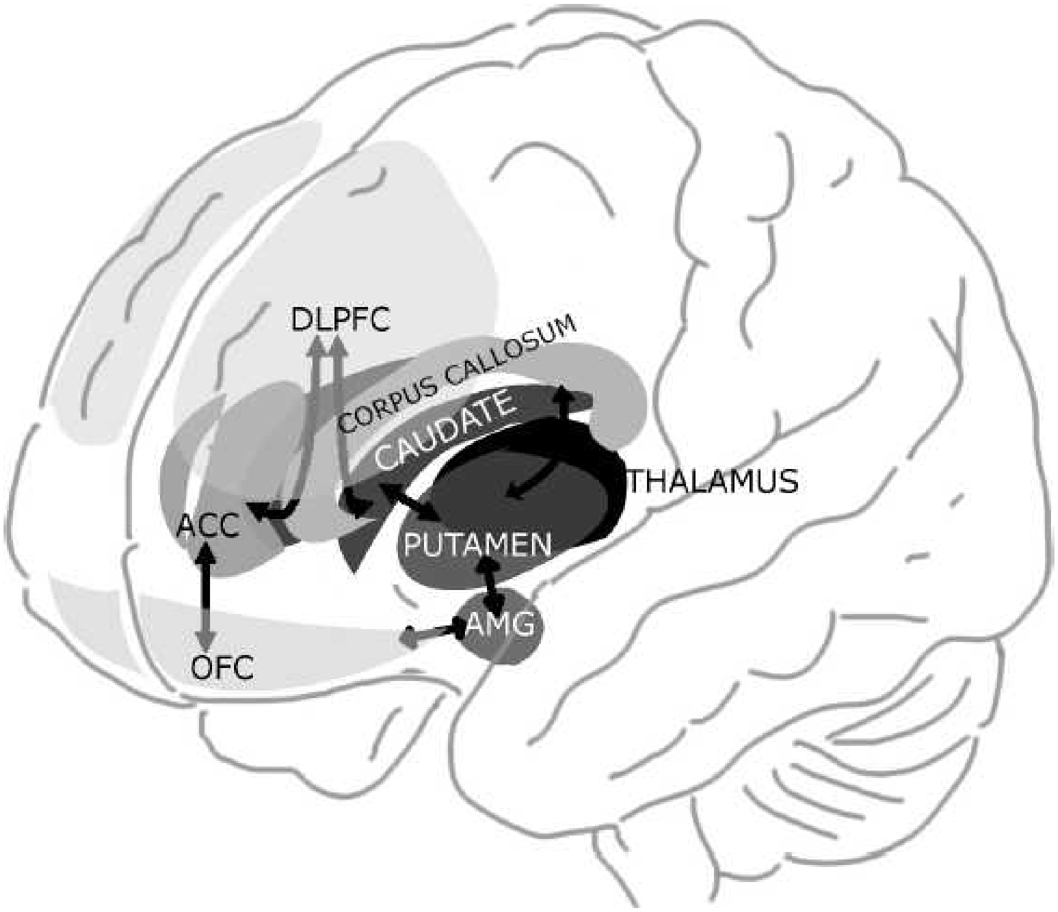

FIGURE 37–12. Brain regions implicated in the pathophysiology of obsessive-compulsive disorder. ACC, anterior cingulate cortex, AMG, amygdala, DLPFC, dorsolateral prefrontal cortex. (Courtesy of Sneha Chenji, Ph.D. Data from Rosenberg DR, MacMillan SN, Moore GJ. Brain anatomy and chemistry may predict treatment response in pediatric obsessive-compulsive disorder. *Int J Neuropsychopharmacol.* 2001;4(2):179–190.)

Prefrontal Cortex. MRI investigation in treatment-naive pediatric patients with OCD as compared to age- and sex-matched healthy controls demonstrated larger anterior cingulate volumes but not DLPFC volume in the OCD patients. These findings are consistent with findings of increased regional cerebral blood flow and metabolic activity in the anterior cingulate cortex in adult and pediatric patients with OCD. Larger anterior cingulate volumes were associated with increased OCD symptom severity but not the duration of illness. Pediatric OCD patients also failed to demonstrate the normal age-related growth in anterior cingulate volume seen in healthy controls (Fig. 37–17). Anterior cingulate volumes were inversely correlated with striatal volumes in the OCD patients. It should be noted that two independent studies noted larger anterior cingulate volumes in pediatric OCD, with the more recent study finding differences in the anterior cingulate gray but not white matter. Lower anterior cingulate Glx was also seen in OCD patients more than in healthy controls. Of interest, the lower anterior cingulate Glx concentration is associated with the G/G genotype of the glutamate receptor gene polymorphism GRIN2B-rs1019385 in OCD patients. A recent fMRI study found greater activation and connectivity of the medial PFC/dorsal anterior cingulate in pediatric OCD patients compared to controls. It was suggested that this might reflect an exaggerated concern for correct performance. Studies of the CC found a larger area and lower signal intensity of the genu of the CC in treatment-naive pediatric OCD patients than in controls. The genu is the region of the CC that connects left and right ventral prefrontal cortical regions, such as the anterior cingulate cortex. This provides further evidence for the involvement of ventral prefrontal cortical regions, such as the anterior cingulate cortex, in the pathogenesis of OCD. In right prefrontal white matter, pediatric OCD patients demonstrated greater NAA and Cho concentrations when compared to healthy control participants. The greater NAA concentration correlated with OCD symptoms as well. Using the manual tracing technique, greater right white matter volume in the orbital PFC has also been noted. Indeed, a recent examination of frontal–striatal–thalamic white matter found greater age-related increases in fractional anisotropy in pediatric OCD patients as compared to controls. In the cingulum bundle, this correlated with OCD symptom severity.

FIGURE 37–13. Schematic diagram showing selected aspects of cortico-striatal pathway loops in **A**: typically developed individuals. **B**: Obsessive compulsive disorder (OCD). **C**: Tourette syndrome (TS). Although some studies have reported normal integrity of striatal dopamine systems, preliminary neuroimaging and postmortem results suggest hyperinnervation of the striatum by dopaminergic neurons, which may contribute to the pathogenesis of tics in TS and compulsions in OCD. Note that in both TS and OCD, there are excessive excitatory projections from the thalamus to cortical areas that mediate the final behavior(s), as noted by the descriptions in the *bubbles* on the left side. These cortical areas are connected to other cortical/subcortical regions involved in the disorders. Excitatory (glutamatergic) projections are indicated by *solid arrows* and inhibitory (GABAergic) projections by *dotted arrows.* Dopaminergic projections are indicated by *outlined arrows*. Thicker arrows indicate increased projections; thinner lines indicate decreased projections. Notably, the details of these pathways across conditions have evolved over time. This figure is intended to provide foundational knowledge on the direct and indirect pathways across typical development and neurodevelopmental conditions. GABA, γ-aminobutyric acid; Gpe, external segment of the globus pallidus; Gpi/SNr, internal segment of the globus pallidus or the substantia nigra pars reticulata; SNc substantia nigra pars compacta; STN, subthalamic nucleus; PFC, prefrontal cortex, Pre-SMA, presupplementary motor area; SMA, supplementary motor area, OFC, orbitofrontal cortex. Brain anatomy and chemistry may predict treatment response in paediatric obsessive-compulsive disorder. *Int J Neuropsychopharmacol*. 2001;4(2):179–190. doi:10.1017/S1461145701002401.)

Thalamus. The thalamus acts as the relay station for neuronal input to the cortex and plays a critical role in the circuitry implicated in imaging studies of OCD. In an MRI study of treatment-naive pediatric patients with OCD as compared to age- and sex-matched healthy controls, OCD patients were found to have larger thalamic volumes. After therapy with the SSRI paroxetine, thalamic volumes decreased in size to the point at which they no longer differed significantly from those of controls (Fig. 37–18). This reduction in thalamic volume was correlated robustly with a reduction in OCD symptom severity (Fig. 37–19). Indeed, a larger pretreatment thalamic volume predicted a better response to paroxetine treatment. When subdividing the thalamus into its component nuclei, the changes in volume were most prominent in medial rather than lateral thalamic regions. With CBT, no significant changes in thalamic volume were observed before and after 12 weeks of treatment in treatment-naive pediatric OCD patients. This suggests that the reduction in thalamic volume may be specific to SSRI therapy as opposed to a more general treatment effect. A large-scale study with 2,551 school-aged children showed that children with probable OCD also have larger thalami than controls, suggesting these differences in thalamic volume may inform longitudinal analyses. In a closer examination of the thalamus in OCD, a ^{1}H-MRS study of treatment-naive pediatric OCD patients and age- and sex-matched pediatric controls was conducted. Lower levels of the neuronal marker NAA were found in OCD patients than in healthy controls. After 12 weeks of drug therapy with paroxetine, an increase in NAA in the medial but not lateral thalamus was seen. Thus, as enlarged thalamic volumes in OCD patients appear to be reduced toward normal after SSRI treatment, lower levels of NAA may be conversely increasing. This suggests a potential neurotrophic effect of SSRI treatment. In addition, significantly greater left and right medial thalamic Cho concentrations were observed in OCD patients than in both healthy control subjects and patients with MDD. Cho concentrations did not differ between patients with MDD and control subjects. This suggests that alterations in medial thalamic Cho differentiate patients with OCD from healthy control subjects and patients with MDD.

Amygdala. Given its role in fear conditioning, the amygdala is believed to be involved in the pathophysiology of OCD. The amygdala is also a target of SSRIs, the mainstay of pharmacotherapy for OCD. In a recent study, amygdala volumes were evaluated for in vivo volumetric changes in 11 pediatric patients with OCD before and after 16 weeks of monotherapy with the SSRI paroxetine. Eleven healthy pediatric control subjects had baseline and follow-up scans, but none of these subjects received medication. OCD patients at baseline demonstrated significant asymmetry of the amygdala (left greater than right) as compared to healthy controls. The volume of the left amygdala decreased significantly following treatment in the OCD patients. This reduction in the volume of the left amygdala in patients correlated significantly with higher paroxetine dose at the time of the follow-up scan and total cumulative paroxetine exposure between the scans. No changes in right or left amygdala volume were noted in healthy controls over time. There are several possible mechanisms that may account for the paroxetine-mediated change in amygdala volume. Disease progression cannot be entirely ruled out, but this is unlikely, given the degree of change noted and the short time in which these changes occurred. The significant inverse relationship between left amygdala reductions and paroxetine treatment lends credence to the idea that the reversal of hypertrophy is due to treatment. Functionally, in most anxiety disorders, an overactive amygdala is often noted. In pediatric OCD, however, amygdala activity is reduced in response to emotional stimuli. Caution is noted due to the small sample sizes involved. Further research is warranted.

Pediatric Autoimmune Neuropsychiatric Disorders Associated With Group A β-Hemolytic Streptococcal Infection

While a smaller basal ganglion appears to characterize patients with early-onset OCD, larger basal ganglia occur in the subset of patients with pediatric autoimmune neuropsychiatric disorders associated with group A β-hemolytic streptococcal (GABHS) infection (PANDAS). In PANDAS, it is hypothesized that GABHS-associated antibodies cross-react with neurons in the basal ganglia. This causes the observed symptoms of OCD, as well as tics/TS and ADHD in susceptible children. This hypothesis is supported by evidence indicating larger basal ganglia volumes in some patients with OCD, tics, and/or ADHD that are positively correlated with the incidence of GABHS infection and the presence of antibody titers. Furthermore, immunotherapy interventions such as plasmapheresis ameliorate OCD symptoms in some PANDAS patients with marked OCD symptoms. Recovery is also associated with a reduction in basal ganglia volumes. Of interest, thalamic volumes do not differ between PANDAS patients and controls. Although additional studies are needed, this suggests possible unique neurodevelopmental subtypes of OCD.

Anxiety Disorders

Compared with OCD, there have been relatively few neuroimaging studies of pediatric anxiety disorders.

Generalized Anxiety Disorder

In children with GAD, regions associated with fear learning and extinction, mentalization, and amygdala regulation (Fig. 37–20) exhibited greater cortical thickness than controls (Fig. 37–21). These areas included the right inferior frontal gyrus and the left inferior and middle temporal gyri. Thinner parietal and occipital areas have been associated with poorer treatment response. Moreover, smaller hippocampal volumes have been shown to correlate with increased anxiety symptom severity. Furthermore, amygdala intrinsic functional connectivity is disrupted in children with GAD, affecting the amygdala’s connections with the medial PFC, insula, and cerebellum. Functionally, greater left medial PFC and right ventrolateral PFC activation was observed in adolescents with GAD in response to a continuous performance task with emotional distractors. Disrupted connectivity arising from the amygdala was also seen. As discussed earlier (see depressive and bipolar and related disorders), the amygdala has extensive interconnections with cortical–limbic circuitry and plays a significant role in the processing of anxiety or fear. Indeed, fMRI studies in a combined sample of children with GAD and/or panic disorder compared to healthy children found exaggerated amygdala activation in response to fearful faces in patients with GAD. Furthermore, amygdala volume was significantly larger in pediatric patients with GAD than in healthy controls. In response to treatment with medication or CBT, right ventrolateral PFC activation related to emotional faces increased. In addition to thicker cortices and larger amygdala volumes, subcortical regions are also affected by GAD. The right putamen was also found to be larger in children with GAD. Interestingly, maltreatment during childhood was associated with larger left thalamic volumes in children with GAD as well. Both the putamen and thalamus have been implicated in other anxiety disorders, but their precise role has yet to be delineated.

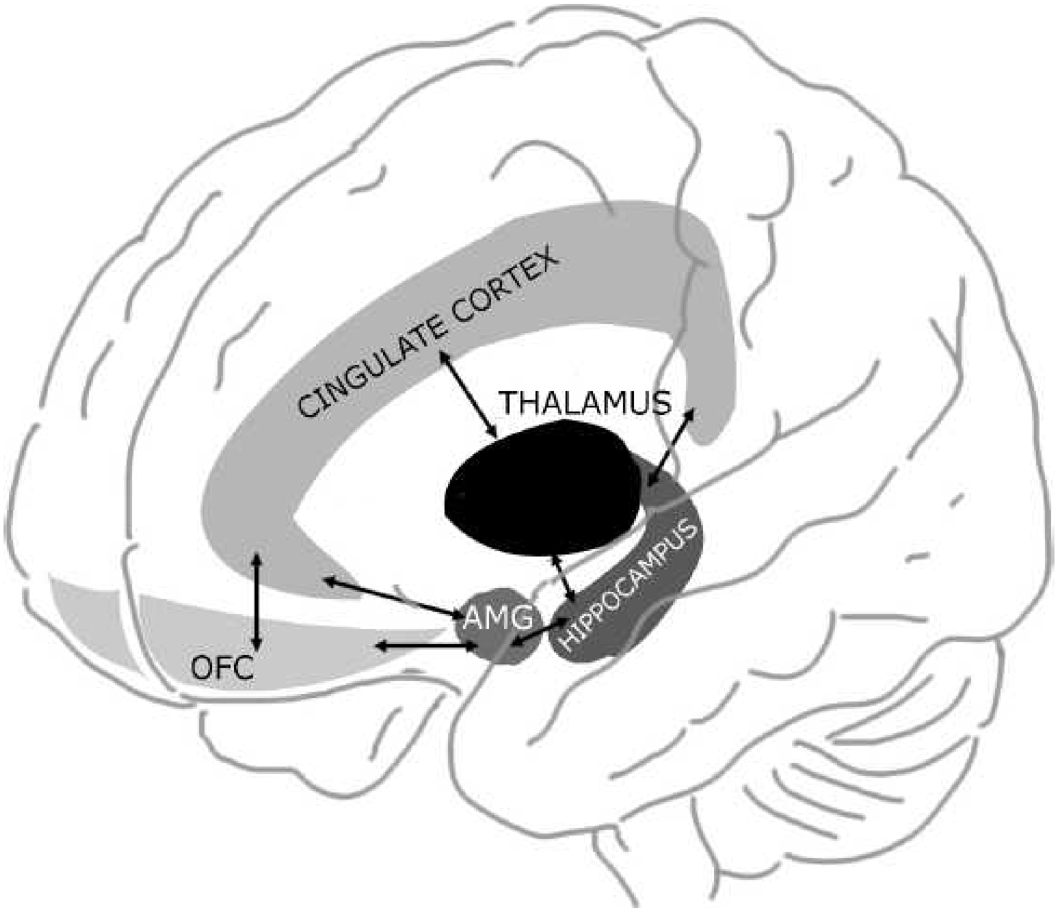

FIGURE 37–20. The thalamus, cingulate, amygdala (AMG), hippocampus, and the orbital frontal cortex (OFC) are activated in the emotion of fear. (Courtesy Sneha Chenji, Ph.D.)

Post-traumatic Stress Disorder

The amygdala has been implicated in some studies of adult patients with PTSD, and recently hypertrophy of the amygdala in children with PTSD has been observed. In addition, smaller hippocampal volumes have been consistently found in adults with chronic PTSD but not in children with PTSD. In children with PTSD, smaller whole-brain, prefrontal cortical, and right temporal lobe volumes are associated with an earlier age of onset and longer duration of abuse. More recently, a ^{1}H-MRS study demonstrated a lower concentration of the neuronal marker NAA in the anterior cingulate cortex of maltreated children with PTSD than in that of controls. Consistent with that finding, a lower concentration of gray matter has been found in youth with PTSD and increased activation in response to a threat in the anterior cingulate cortex. Given the mixed evidence, discrete neurobiologic profiles may be present in pediatric versus adult patients with PTSD. Longitudinal studies to characterize the developmental neurobiology of the illness are needed. Careful assessment for comorbid conditions—for example, anxiety and depression—are also necessary to discern unique neurobiologic pathways among different anxiety disorders and depression.

Tourette Syndrome

TS is often comorbid with ADHD and OCD. Indeed, certain brain circuits are common in the pathogenesis of all three conditions.

Cortex. A recent large-scale volumetric MRI study of children and adults with TS found striking abnormalities in cortical development. In the parieto-occipital region, a greater volume was observed in children than in adults with TS. Age-associated reduction in parieto-occipital volumes occurred predominantly in females. In contrast, relatively larger parieto-occipital volumes were observed in older men with TS, suggesting that sexually dimorphic neurodevelopment may contribute to the greater prevalence of TS in males than in females. Larger DLPFC volumes were found in the younger TS patients but tended to decrease toward adulthood. Because tics often diminish with age, smaller dorsolateral prefrontal cortical volumes in older TS patients were hypothesized to reflect the relatively unusual persistence of tics in the adults participating in the study.

fMRI studies demonstrating increased activation of the PFC during tic suppression in adult TS patients suggest that larger prefrontal cortical volumes observed in children with TS may represent healthy structural compensation to allow for tic suppression. Functional neuroimaging studies in healthy children and adults have implicated the orbital PFC in the processing of inhibitory control, such that the inverse correlation between orbital prefrontal volumes and tic severity in children and adults with TS likely reflects a fundamental deficit in inhibitory control allowing for the “release” of tics. In the motor and premotor cortices, increased volumes and functional activity appear to occur in adults but not children with TS, possibly reflecting the cumulative effect of years of repetitive, abnormal movements. More recently, it was noted that the normative developmental correlates of activity in fronto-striatal circuits that subserve self-regulatory control are disturbed in persons with TS.

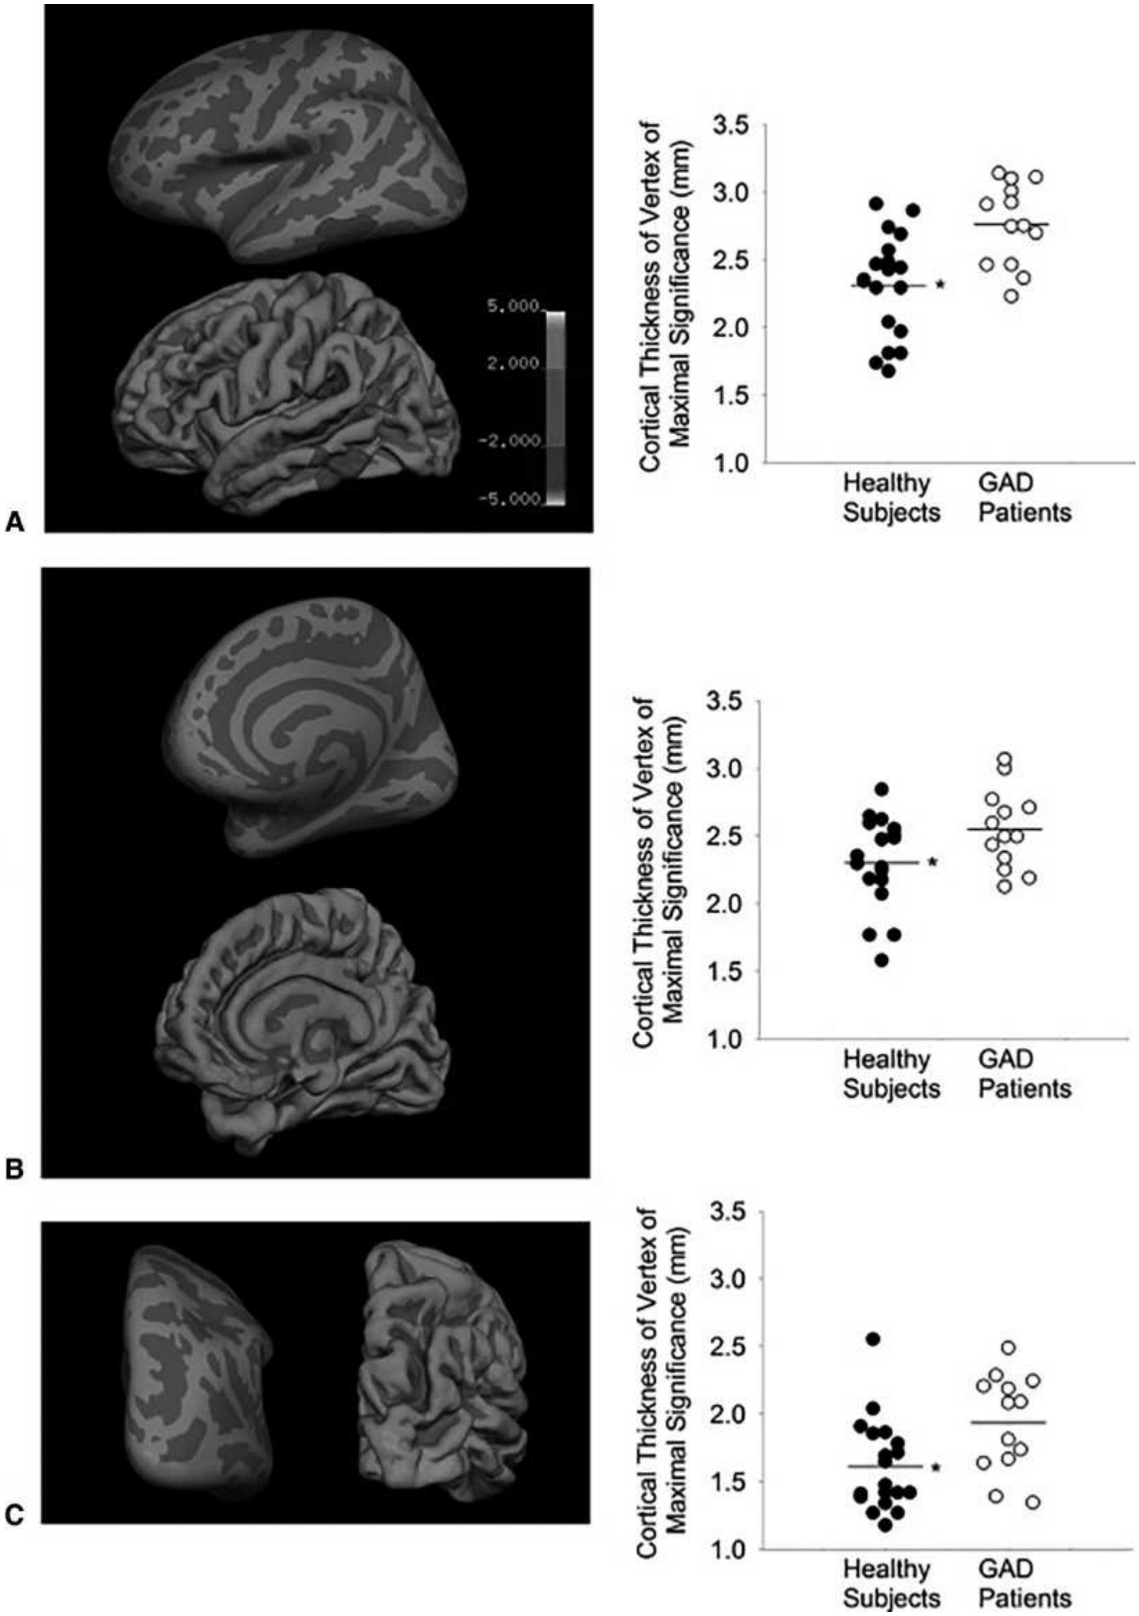

FIGURE 37–21. Cortical thickness in adolescents with generalized anxiety disorder (GAD) as compared to healthy controls. Warm colors (*red to yellow*) indicate greater cortical thickness in adolescents with GAD compared to

healthy comparison subjects, and for each region, both cortical and inflated views are presented. Scatter plots are shown for the maximally significant vertex within each depicted region and healthy patients are represented by (•) while adolescents with GAD are represented by (°). The left temporal findings are shown in panel **A**, while the prefrontal differences and occipital findings are shown in panels **B** and **C**, respectively. Finally, an *asterisk* denotes a statistically significant difference between groups (*P* = .006 for the left temporal differences; *P* = .0004 for the frontal differences, and *P* = .0001 for the occipital differences). (See eBook for color image.) (Reprinted from Strawn JR, John Wegman C, Dominick KC, Swartz MS, Wehry AM, Patino LR, Strakowski SM, Adler CM, Eliassen JC, DelBello MP. Cortical surface anatomy in pediatric patients with generalized anxiety disorder. *J Anxiety Disord.* 2014;28(7):717–723. doi: 10.1016/j.janxdis.2014.07.012.)

Basal Ganglia. Reduced basal ganglia volumes have been observed in both children and adults with TS. Volume reduction has been found to be particularly prominent in the globus pallidus and putamen in patients with TS, implicating motor pathways within cortical–subcortical circuitry. This is consistent with the motor phenomena of tics. In support of the hypothesized role of sex in the neurobiology of TS, abnormal basal ganglia asymmetry has been demonstrated in boys but not girls with TS. Although volumetric neuroimaging studies of identical twins with TS have generated conflicting findings, one twin study found a greater reduction of the caudate in the more severely affected twin, suggesting that the neurobiologic underpinnings of TS expression may be influenced by environmental exposure, as well as by sex and genetic predisposition. Enlargement of thalamic volumes has also been noted in children and adults with TS as compared to healthy comparison subjects. Increased apparent diffusion coefficient (ADC) in cortico-striatal projection pathways, including the left external capsule and left and right subcallosal fasciculus pathway, have also been noted in children with TS. Based on the efficacy of dopamine receptor blockade in the treatment of TS, one recent PET study of children with TS found evidence for excessive dopamine decarboxylase activity in the left caudate and right midbrain, suggesting subcortical dysfunction of the dopamine system in pediatric patients with TS (see Fig. 37–12).

Corpus Callosum. Conflicting results have been observed with regard to the CC in TS in youth, with reports of larger, smaller, and no difference in the area. A study of monozygotic twins discordant for TS using both MRI and DTI methods failed to observe differences with regard to fiber-tracking to the CC. Fractional anisotropy was lower in the posterior aspects of the CC in the affected twin, however, indicating a less-coherent level of organization.

Other Brain Regions. A recent structural MRI investigation evaluated the association between the size of the cavum septi pellucidi (CSP) and a diagnosis of TS. They found a smaller CSP in children with TS than in healthy pediatric controls. These findings were replicated in an independent sample of adult patients with TS as compared to healthy adults. An inverse association between CSP size and ADHD symptom severity was also noted. In addition, the overall volume of the hippocampus and amygdala was found to be significantly larger in the TS group than in controls. A surface analysis found that the larger volumes in the TS group were derived primarily from the head and medial surface of the hippocampus and the dorsal and ventral surfaces of the amygdala. The volumes of these subregions declined with age in the TS group but not in the controls. Hence, the subregions were significantly larger in children with TS but significantly smaller in adults with TS than in controls. Clinically, volumes in these subregions correlated inversely with the severity of tic, OCD, and ADHD symptoms in patients. This suggests that the enlargement of the subregions may have a compensatory effect on tic-related symptoms.

Childhood-Onset Schizophrenia

Although it is a rare condition, COS has recently been the focus of considerable research investigation. It is believed that an enhanced understanding of the developmental brain changes in early-onset schizophrenia might lead to an improved understanding of the neurobiology of adult schizophrenia. Indeed, using brain region data as input, machine-learning methods can correctly classify COS and healthy controls with 73.7% accuracy.

Total Brain Volume, White Matter, and Ventricles. Aside from disrupted hypothalamic–pituitary–adrenal (HPA) axis function in mood disorders, one of the most consistent findings in psychiatry is a reduction in total brain volume and an increase in the volume of the ventricles in adult patients with schizophrenia. In COS, the smaller total brain volume is even more dramatic than in adult patients. This suggests that COS may be a rare, more severe version of the disease. Smaller total brain volume in COS is accompanied by ventriculomegaly (i.e., enlarged ventricles). The smaller amount of brain tissue in early-onset schizophrenia may result from a progressive loss of both gray and white matter in periventricular regions, including the posterior cingulate, caudate, and thalamus (Fig. 37–22).

In young patients with COS, slower growth rates were observed in parietal white matter. However, the CC did not demonstrate any differences from controls with regard to volume and growth trajectory. Furthermore, patients with COS have demonstrated reduction in fractional anisotropy in the cuneus when compared to healthy controls. This reduction was also observed in their healthy siblings, possibly indicating some shared genetic risk. This indicates regional effects on white matter with COS.

PFC, Insula, and Temporal Lobe. Akin to the aforementioned finding in the cuneus, during a weather prediction fMRI task, siblings of COS patients demonstrated less activation of the frontal and striatal regions compared to controls. This indicates that impairments in cortical–striatal function may play a role in the liability of schizophrenia. It has been suggested that changes in frontal deficits are modulated in part by polymorphism of the *catechol-o-methyltransferase* (*COMT*) gene. Lower levels of the ^{1}H-MRS neuronal marker NAA and gray matter volumes in the frontal and anterior cingulate cortex are found in patients with COS and unaffected offspring of patients with schizophrenia at increased risk for developing schizophrenia as compared to controls. This suggests that an exaggerated pruning of neurons may be involved in the pathogenesis of schizophrenia. Controlling for medication exposure in neuroimaging studies is critical because typical neuroleptics have been shown to decrease frontal cortical activation, whereas atypical agents (e.g., risperidone) increase frontal activation. The insula plays a critical role in delineating self from nonself-stimuli. Given this function, it has been implicated in the positive symptoms associated with schizophrenia. In 98 patients with COS contrasted with 100 healthy control participants, smaller right and left insula volumes were noted in patients. Right insula volume correlated inversely with positive symptoms in patients with COS.

Consistent with studies of adult patients with schizophrenia, a smaller volume of the temporal lobe has been reported in COS, although a contradictory report exists. Within the temporal lobe, smaller superior temporal gyrus volumes associated with increased symptom severity have been observed in patients with COS as compared to healthy controls. In adult patients with first-episode schizophrenia, volume reduction in the superior temporal gyrus was correlated with the duration of pretreatment illness. Superior temporal gyrus volumes appear to increase toward normal after pharmacotherapy, suggesting that this region may be integral to symptom expression in schizophrenia. In a recent report, it was noted that patients with COS showed significant bilateral deficits (9% to 10%) in total hippocampal volume. This smaller volume in such patients remained consistent from age 9 to 26 years. Of interest, subregional maps showed heterogeneous changes, with a loss of hippocampal volume in both anterior and posterior ends, whereas the body of the hippocampus gained in volume. This suggests that the subunits of the hippocampus are differentially affected in schizophrenia. Indeed, a reduction in the volume of the amygdala–hippocampal formation has also been demonstrated in adults with first-episode schizophrenia, in patients with COS, and in offspring and siblings of patients with schizophrenia. The reduction in amygdala–hippocampal formation in patients with COS and high-risk unaffected relatives suggests that it might play a critical role in the pathogenesis of schizophrenia. Earlier onset of illness in patients with traumatic perinatal histories has also been shown to be associated with a more severe reduction in amygdala–hippocampal volume. Shape analysis revealed a striking inward deformation in the anterior hippocampus in patients with COS. These inward deformations were associated with positive symptoms. More recently, it has been noted that the younger, healthy siblings of patients with COS showed significant gray matter deficits in the left prefrontal and bilateral temporal cortices and smaller deficits in the right prefrontal and inferior parietal cortices compared with controls. It may be that a loss in prefrontal and temporal gray matter in COS is a familial/trait marker of the illness.

Subcortical Regions. Increased caudate volume has been reported in COS, although this might be due to typical neuroleptic exposure. When typical neuroleptics were replaced with clozapine in patients with COS, caudate size decreased to normal within 2 years. However, caudate volume reduction has been reported in neuroleptic-naive adult patients with schizophrenia, so that a primary alteration in caudate volume cannot be ruled out. Recently, a shape analysis of the caudate in COS found an outward displacement in the dorsal aspect of the caudate body. One of the most consistent findings in psychotropic-naive young adults with schizophrenia and COS is decreased volume of the thalamus. Reduced thalamic volumes have also been found in the primary relatives of patients with schizophrenia.

Substance-Related and Addictive Disorders

Alcohol Use Disorder. Given the high prevalence of conditions such as binge drinking among adolescents, the need for research in this area is great. Consistent with adult studies, a neuroimaging study of alcohol use in adolescents found a significant volume reduction in bilateral hippocampi as compared to healthy pediatric controls. Hippocampal volume reduction correlated positively with age of onset and negatively with duration of alcohol use, suggesting that alcohol may interfere with normal growth of the hippocampus. Smaller prefrontal gray and white volumes have been noted in adolescents who abuse alcohol. In youth at high risk for alcoholism, a smaller amygdala has been consistently noted. This is suggestive of a possible abnormality in the processing of fearful stimuli. An fMRI connectivity study found differences in resting state synchrony between the left nucleus accumbens and bilateral inferior frontal gyri and the left postcentral gyrus in youth at risk as compared to healthy controls. The results suggested that youth at risk had less segregation between the nucleus accumbens and frontal executive functions and less integration with reward-related areas like the orbital frontal cortex. Aligned with this, another study with 150 adolescents showed that Alcohol Use Disorder symptomology was associated with activation in other brain areas mediating reward and punishment (i.e., striatum, anterior cingulate cortex). ^{31}P-MRS has been used to probe for metabolic abnormalities of frontal, occipital, and parietal cortex. In children with both a positive family history of alcoholism and a disruptive behavior disorder, decreased PDE levels were observed, suggesting abnormalities in energy metabolism.

These abnormalities were also associated with learning disability. In a longitudinal morphometric study, 40 adolescents were followed over 3 years. During that period, half initiated heavy drinking. At baseline, subjects who later started drinking heavily had smaller left cingulate, pars triangularis, and rostral anterior cingulate volume as compared to those who did not. Over time, reductions in left inferior and middle temporal gyri, left caudate, and brain stem were noted as compared to substance-naive youth. This study suggests that there are preexisting markers in future drinkers and a further volume reduction over time after alcohol abuse was initiated.

Cannabis Use Disorder. Cannabis-using adolescents demonstrate thinner left and right supramarginal, left and right inferior parietal, right pars triangularis, left pars opercularis, left superior frontal, and left superior temporal cortical thickness compared to noncannabis-using subjects. Greater cannabis use was also associated with thicker bilateral superior frontal gyri. In adolescents who are regular cannabis smokers, gray matter volume reduction was observed in the medial temporal cortex, temporal pole, parahippocampal gyrus, insula, and orbitofrontal cortex. These are brain regions rich in cannabinoid CB1 receptors and associated with motivational, emotional, and affective processing. In 17 chronic cannabis-using adolescents as compared to 17 healthy controls, reduction in anterior cingulate NAA, Cr, inositol, and glutamate were observed. Akin to what was observed in childhood-onset schizophrenia, changes in prefrontal and insula cortical thickness were observed in adolescent cannabis users. In a resting state connectivity study, heavy cannabis use in adolescents was also associated with middle frontal gyri activity and inversely with the middle temporal gyrus. During an fMRI monetary incentive delay task, adolescent males who use cannabis showed striatal hyperactivity in anticipation of reward. A systematic review of diffusion-weighted imaging studies of cannabis use during adolescence found abnormal white matter microstructure in neocortical association pathways as well as in projection and thalamic pathways. One of the primary problems with studies of cannabis use in adolescents is the limited ability to quantify and control for exposure; with most studies relying on self-report of use with little data on the strength of cannabis used.

Feeding and Eating Disorders

Several studies have documented decreased global brain volume in children and adolescents with anorexia nervosa (AN), which may be somewhat reversible. However, decreased large-scale brain volume loss is probably the result of malnutrition and is not, therefore, likely to be particularly helpful in elucidating the neurobiologic underpinnings of AN. In adolescents with AN, a lower concentration of frontal NAA has been noted than in controls. Of interest, a lower frontal PDE level was reported as well, indicating a possible decrease in the fraction of MPLs. Furthermore, adult females with AN show a reduction in glutamate in the anterior cingulate cortex, occipital cortex, and putamen. However, spectroscopy studies have yielded conflicting results overall and are limited for other eating disorders. fMRI studies show greater activation in AN, bulimia nervosa, and binge eating disorder patients than in controls when viewing food-related stimuli and/or making choices about food. However, these findings have been mixed for the latter two groups. During working memory tasks, greater activation of temporal and parietal areas was noted in adolescents with AN that resolved with treatment. Functional studies of reward and punishment have also shown that adolescents with AN are especially responsive to losses compared to wins. It has been suggested that altered response to reward in adolescents with AN may be due to disturbed dopaminergic dysfunction, but that has yet to be thoroughly explored. Similarly, a study of 122 adolescent females revealed a positive relationship between brain activity in response to winning money and binge eating behaviors. Studies of bulimia nervosa have also noted reductions in frontal and temporal regions in affected adolescents compared to healthy subjects. Furthermore, fMRI data indicate that adolescents with bulimia nervosa demonstrate abnormal patterns of activation during tasks tapping into regulatory control and conflict resolution—with frontal and striatal regions failing to activate. Individuals with bulimia nervosa and individuals with binge eating disorder also show hypoactivation in fronto-striatal circuits. Finally, adolescents with bulimia nervosa also show increased engagement (compared to controls) in areas that mediate attention and self-referential thoughts when at rest, which might be related to excessive concerns about body shape and weight in this group.

Autism Spectrum Disorders

The number of imaging studies investigating the underlying neurobiology of ASDs has increased eightfold since 2003 (Fig. 37–23). This tremendous progress occurred despite inherent limitations. First, there have been advances in scanning young children (see Table 37–1). Early studies into ASD were hampered by being conducted in adults or adolescents. Use of mock scanners and thoughtful approaches to the scanning procedure have allowed very young children to participate. Given that typical onset of ASD is by 3 years of age, studying mostly older patients places the research at an obvious disadvantage. Second, the majority of neuroimaging studies, especially fMRI studies, have been conducted in high-functioning patients with ASD. Differences in study populations, medication exposure, and methodologic differences in image acquisition and analysis may have also contributed to the lack of reproducibility of findings.

Global Brain Abnormalities. It is believed that alterations in global brain growth are involved in the pathogenesis of ASD. Greater total brain volume has been one of the more consistent findings in patients with ASD. When examining functional connectivity, it appears that in adolescents and adults with ASD, connectivity is reduced. In younger children with ASD, however, intrinsic functional connectivity is increased. These findings have resulted in a call for research on the effect of puberty on the neurobiology of ASD. In a large-scale study (*N* = 717) of children 6 to 10 years of age, those with higher autistic traits (scores on the social responsiveness scale) demonstrated widespread areas of decreased gyrification. Whole-brain serotonin synthesis capacity has been measured in 2- to 15-year-old children with ASD with PET studies using the tracer α-[^{11}C] methyl-L-tryptophan (^{11}C-AMT) for PET. Children with ASD were compared to healthy siblings without ASD and to epileptic children without ASD because using PET to study the brains of healthy pediatric controls is rare. Sedation was required for all of the children with ASD or epilepsy and for many of the siblings without ASD who underwent PET scanning. Disruption in serotonin synthesis capacity was observed in children with ASD compared to their siblings and children with epilepsy. In normal children, whole-brain serotonin synthesis capacity was greater than 200% of adult capacity until age 5 years, and then it declined to adult levels, whereas in children with ASD, serotonin synthesis capacity increased very gradually from age 2 to 15 years to levels 1 to 1.5 times normal adult values.

Considerations for Brain Imaging Research

Common Questions	Considerations
Which brain measures should I use?	Think about your research question, are you interested in brain structure, chemistry, or function? Which is more important for your work—the spatial or temporal sensitivity? If you are using brain imaging to track short-term prognosis or treatment effect, brain function, chemistry, or temporal sensitivity is robust compared to brain structure. If you are interested in development or long-term prognosis, any of these measures will be useful. However, keep in mind, the brain changes rapidly during childhood and adolescence in as little as 6 months.
What parameters should I choose?	Consider your time and budget for the type of imaging modality you choose. Check for recent and relevant literature. Reflect on and integrate the parameters they have used—are these parameters feasible for your study, given the budget and time? There are general resources that have been published previously discussing MRI and EEG parameters extensively.
What is the ideal sample size?	This is going to depend on your study design. Identify effect sizes based on recent meta-analyses and use statistical tools to determine sample size, required power or alpha value a priori based on your study design or analysis.

Note that effect sizes for brain imaging are generally low, which means that large sample sizes might be required for statistical significance.

Regional Brain Alterations. In addition to global brain alterations in serotonin synthesis, comparisons of children with ASD who were otherwise healthy without seizures and their siblings without ASD showed asymmetries in serotonin synthesis in frontal cortex, thalamus, and cerebellum. Lower serotonin synthesis was observed in the left frontal cortex and thalamus in children with ASD. Lesser accumulation of ^{18}F-DOPA in the anterior medial PFC was observed in medication-free children with ASD. Lower levels of DLPFC phosphocreatine, as measured by ^{31}P-MRS, in high-functioning adolescent and young adult men with ASD suggest altered metabolism and increased membrane degradation in this region were correlated with neuropsychological and language deficits. The temporal lobe plays a critical role in emotion processing. Hence, it is not surprising that pediatric ASD has been associated with lower metabolic rate, perfusion, and NAA in temporal regions. Volumetric studies of the amygdala and hippocampus have been inconsistent in ASD. In the cerebellum, the dentate nucleus has also been implicated in ASD. The dentate nucleus is involved in the regulation of language and motor output. Abnormal activation of the right dentate has been observed in patients with ASD when performing a language task. In response to sensory stimuli, along with the expected sensory areas, the hippocampus, amygdala, and orbital frontal cortex demonstrate hyperactivity in youth with ASD. Furthermore, greater brain serotonin synthesis has been reported in the right dentate nucleus. Reductions in the neuronal marker NAA in the dentate as measured by ^{1}H-MRS have also been reported. Finally, a large-scale examination of 1,571 individuals with ASD revealed larger lateral ventricle and intracranial volume, increased frontal and decreased temporal cortical thickness, as well as lower subcortical volumes of the pallidum, putamen, amygdala, and nucleus accumbens compared to 1,651 controls. The trajectory of these subcortical volumes was associated with age, peaking during adolescence before decreasing in adulthood.

Specific Learning Disorders

The left hemisphere plays a critical role in the development of reading skills in healthy children. This function appears to be impaired in children with a reading disability, as suggested by lower functional activation in dorsal and ventral regions. Indeed, similar results have been noted in adults with a reading disability, with less functional connectivity between these circuit substrates.

More recently, bilateral prefrontal regions that link brain regions associated with phonologic awareness and rapid naming also demonstrated abnormal functional connectivity in children with dyslexia. The planum temporale is associated with a number of auditory and language-related processes. In children with dyslexia, the planum temporale demonstrates a greater rightward asymmetry. Perhaps to compensate for this dysfunction, children and adults with a reading disability “overactivate” the DLPFC, including the inferior frontal gyrus. Adults with a reading disability also engage the parallel circuitry in the right hemisphere. Right hemisphere activation during reading is normal in children but typically diminishes into adulthood. This suggests a change in the lateralization that characterizes the neural substrates that mediate reading in individuals with persistent reading disability.

FUTURE DIRECTIONS

The use of neuroimaging in children with psychiatric diseases provides an exciting opportunity to explore the developmental abnormalities that lead to mental illness (see Table 37–4). Neuroimaging studies in childhood-onset neuropsychiatric disorders that use biomarkers as both moderator (present at baseline) and mediator (changing with treatment) may potentially result in an enhanced mechanistic understanding of the pathogenesis and maintenance of these illnesses, which could lead to better diagnostic and treatment approaches. One such approach might include the identification of a neurobiologic treatment target for novel treatment tools, such as brain stimulation. Disentangling the impact of comorbidities on disorders and how many disorders seem to converge along key brain regions and circuits is also of great importance. MR-based technologies are particularly useful in youth because they entail no radiation exposure and can be successfully applied longitudinally. Although technologic advances will undoubtedly continue to provide more precisely resolved images, investigators must pay special attention to developing consistency in methodologic approaches across studies, along with larger sample sizes to account for the high variability of brain volume and function during childhood and adolescence. With the advent of large-scale, longitudinal, publicly available neuroimaging datasets, together with continual advancements in technology, ample opportunities lie ahead to unravel the pathophysiology and mechanism of treatment response in various childhood-onset neuropsychiatric disorders.

Temperament: Risk and Protective Factors for Child Psychiatric Disorders

David C. Rettew, M.D.

Individuals differ in the types and intensity of their emotional and behavioral responses to various environments. Some people are quick to experience anger or anxiety, whereas others are more laid back. Some people seek out new and exciting experiences, whereas others prefer a predictable routine and the comfort of a few familiar friends. Some people are able to delay their impulses and overcome obstacles while working toward a long-term goal, whereas others become quickly distracted or frustrated. These widely recognized human qualities refer to temperament or personality traits that, along with physical and cognitive dimensions, distinguish one person from the next.

Scientists have been observing and studying child temperament and personality development for many years. The bulk of this work has existed beyond the view of most mental health clinicians, under the notion that this area was distinct from clinical psychiatric disorders. Accumulating research, however, has demonstrated strong links between various temperamental traits and nearly all types of psychopathology. The prevailing question today no longer is *if* temperament is associated with psychopathology but *how* temperament interacts developmentally in shaping children toward and away from serious psychiatric disturbance. This chapter offers a brief overview of temperament, including its history, definition, core dimensions, stability, and underlying neurobiology. Following these sections is a summary of the known relations between specific temperamental traits and specific psychiatric disorders. Finally, the chapter concludes with a discussion of possible mechanisms through which temperamental traits operate to increase risk or, conversely, promote wellness and resiliency throughout development.

HISTORICAL ANTECEDENTS

When most students think of temperament, the two names that often arise are child psychiatrists Stella Chess and Alexander Thomas, who brought the concept of temperament and its role in developmental psychopathology into the spotlight more than 50 years ago. While their work remains pivotal, the foundations of temperament theory can be traced back in time much further. The ancient Greek physician Galen postulated the existence of four temperament types, which he called sanguine (extraverted and stable), choleric (extraverted and unstable), melancholic (introverted and stable), and phlegmatic (introverted and unstable), based on the relative concentrations of four "humors" (blood, yellow bile, black bile, and phlegm). Although this early conceptualization of temperament may appear somewhat comical by today's standards, a thought experiment that substitutes the four humors with modern neurotransmitters such as serotonin and norepinephrine reveals how much of this framework remains intact. Indeed, the very word "temperament," derived from the Latin *temperare*, which means "to mix," conveys this association between the functioning of important biologic substrates in the brain and basic human behavioral and emotional predispositions.

Fast forward to the 20th century and the dawn of modern psychiatry: it is worth noting that Sigmund Freud made few qualitative distinctions between the origins of normal personality traits and the factors responsible for psychiatric symptoms, although the nature of those forces were certainly not described as temperament based. As the tenets of behaviorism and learning theory gained prominence, there again were few distinguishing features between the postulated mechanisms underlying personality and those that caused the formation of psychiatric disorders.

It was in this climate during the 1950s that Chess and Thomas began their work on temperament. Based on interviewing parents and observing children across many years, they proposed nine basic dimensions of temperament, as shown in Table 38–1, and three temperament types—easy, slow to warm up, and, most famously, difficult. These basic elements of temperament were hypothesized to be substantially heritable rather than based on learning or unconscious conflicts. It was this heritable quality of temperament that ran against the prevailing wisdom of both the psychoanalytic and the behavioral schools of thought, and the work of Chess and Thomas was initially subjected to intense criticism.

Through the 1980s and continuing today, a medical model of psychiatric illness began to emerge. Under this framework, disorders like depression or panic disorder arise like other medical illnesses such as diabetes or the flu. Genetic variations and environmental pathogens are viewed as important etiologic factors in this model, and the disorders are conceptualized as binary entities that a person does or does not possess. While such an approach acknowledges the influence of more innate dispositional factors, this disease model of psychiatric disorders also divorces an individual's symptoms from their temperament. A panic disorder, for example, is an illness that "comes out of nowhere" rather than being related to a temperamental proclivity toward experiencing fear.

Definition of Temperament

Individual differences in basic reactivity and self-regulation include the following elements:

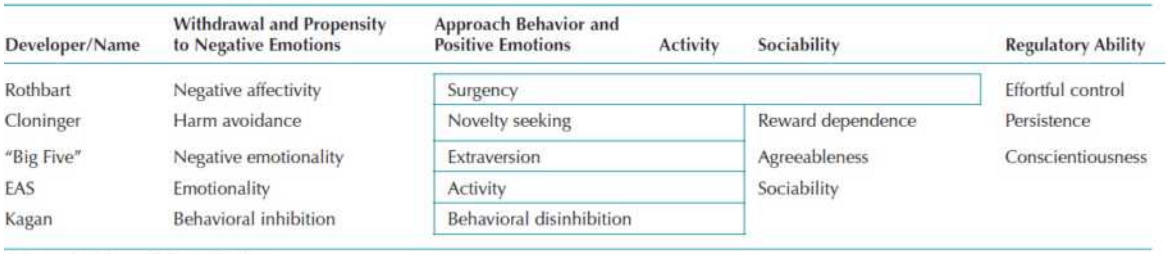
1. Heritability: temperamental traits are often passed on from one generation to the next through both genetic and environmental mechanisms.
2. Early appearance: the antecedents, if not the full traits, are evident in infancy and toddlerhood.
3. Stability: although there is certainly the potential for change, temperamental traits are moderately stable across many years.

Thus, researchers and clinicians interested in temperament continue to challenge and be challenged by the changing models and theories of psychiatric disease. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), while specifically acknowledging the dimensionality of most emotional–behavioral symptoms, retained a disease model of psychopathology in its operational structure. The implications of this decision will be discussed later in this chapter after additional background information on temperament is provided.

DEFINITION OF TEMPERAMENT

Despite the long history of temperament investigation, the precise definition of temperament remains elusive. One prominent temperament researcher, Mary Rothbart, described temperament as “constitutionally based individual differences in reactivity and self-regulation.” Although the debate continues, there exists some consensus on key components of a temperamental trait. First, there needs to be a heritable basis to the trait. This quality does not mean that temperament is purely genetic, but rather that there is at least some genetic influence on the phenotypic expression of that trait. Second, a temperament dimension also needs to be relatively stable across time. Similar to the point about genetic influence, stability does not mean inflexibility or, certainly, destiny, but rather that the trait at one time point can predict future time points even many years into the future. Finally, a temperament dimension is expressed early in life, with its rudiments evident as early as infancy. This latter characteristic distinguishes temperament from other important human qualities, such as life satisfaction or generosity, which incorporate higher cognitive functions. These aspects of temperamental traits are summarized in Table 38–2.

Table 38–3.
Current Dimensions of Temperament and Personality



Developer/Name	Withdrawal and Propensity to Negative Emotions	Approach Behavior and Positive Emotions	Activity	Sociability	Regulatory Ability
Rothbart	Negative affectivity	Surgency			Effortful control
Cloninger	Harm avoidance	Novelty seeking		Reward dependence	Persistence
"Big Five"	Negative emotionality	Extraversion		Agreeableness	Conscientiousness
EAS	Emotionality	Activity		Sociability	
Kagan	Behavioral inhibition	Behavioral disinhibition			

EAS, emotionality, activity, sociability.

MAJOR DIMENSIONS

The core dimensions of temperament continue to be a source of discussion. As previously described, Chess and Thomas hypothesized nine core temperament dimensions and three temperamental types, with the latter referring to a constellation of traits that often coexist as a specific profile. Subsequent testing using different samples and more sophisticated statistical modeling have supported many of these dimensions, whereas others were found in need of modification.

Currently, there exist a number of alternate, even competing, frameworks that have received some empirical support for their reliability and validity. Most temperament taxonomies are structured around basic incentive response systems of approach and withdrawal often merged or crossed with emotional valence (propensities toward positive and negative emotions). Across these various taxonomies, however, there exist named dimensions that overlap somewhat but not completely with a corresponding dimension in another theoretical model. The temperament trait of novelty seeking as described by Cloninger is similar but not identical to a dimension referred to by Rothbart and colleagues as extraversion or surgency. Adding additional complexity is a dimension's relative place along a hierarchical organization from lower- to higher-order traits. Activity level, for example, exists as a component of the surgency dimension in Rothbart's framework but functions as a broad higher-order dimension in the Buss and Plomin model. Furthermore, differences of opinion exist between the conceptualization of temperament traits as quantitative factors that are distributed normally along a continuum versus more binary yes/no designations. All of these variations between the different models of temperament that exist today provide a rich environment for further research and discussion but can be challenging when trying to compare findings across studies. These conceptual challenges notwithstanding, several temperament dimensions are fairly consistent across different nomenclatures and constitute the highest level of temperamental traits. These traits are depicted in Table 38–3.

Clearly, there is a tremendous amount of overlap between the core dimensions of temperament and personality, and a full discussion comparing these two domains is beyond the scope of this chapter. Briefly, it is probably fair to say most temperament and personality theorists view temperament as one of the core foundations of personality, with the latter being further developed through additional life experiences, cultural influences, and cognitive abilities. Because these influences act on children and adults alike, however, a clear boundary between a temperament and a personality trait is obscure and somewhat akin to pinpointing exactly when someone is, for example, an adult. At the same time that some prominent personality researchers such as Costa and McCrae argued that their personality dimensions can largely be seen as temperament, child researchers found evidence that the “Big Five” taxonomy of personality is largely applicable in youth samples. These efforts suggest that at least some of the historical distinction between these two constructs was semantic and based on the age of the sample being studied with the term temperament being applied to children and the term personality applied to adults.

Withdrawal and Propensity to Experience Negative Emotions

A common core dimension in temperament found across many different taxonomies refers to a child’s threshold to experience negative emotions such as sadness, fear, or anger, the intensity of that emotion when triggered, and the duration of that emotional experience. This trait has been described using a number of different labels, including negative affectivity, emotionality, and neuroticism. Some researchers have described a similar trait that reflects an underlying sensitivity to signals of punishment and have referred to this dimension as harm avoidance or the behavioral inhibition system (BIS). Some evidence supports greater separation between the tendency to experience anger and frustration and the tendency to experience fear or anxiety. Nonetheless, components of this dimension often include elements such as worry, shyness, irritability, and difficulty being soothed once aroused. This trait also figured heavily in the Chess and Thomas designation of the “difficult” child.

Approach and Positive Emotions

The other temperament dimension that exists throughout various taxonomic structures refers to the degree to which a person actively engages the world and other people. This trait often also encompasses a tendency to experience positive emotions such as joy and excitement. Additional components of this dimension according to the various frameworks include elements of dominance, preference for high-stimulus activities, and approach behavior. Especially when considered in a more social context, this trait is often referred to as extraversion, whereas from a slightly broader perspective, it has been labeled novelty or sensation seeking or the behavioral activating system (BAS).

Emotional Regulation and Constraint

The third dimension common to most temperamental systems relates to emotional and attentional regulation especially in the face of obstacles or in the pursuit of a long-term goal. As a separate dimension, it has been referred to as effortful control, persistence, or, under the “Big Five” framework, conscientiousness. Children with lower levels of this trait are often described as impulsive, distractible, and disorderly. Parallels to more philosophical terms encompassing a person’s degree of voluntary control such as “will” are apparent and distinguish this dimension from behavior that is restrained by anxiety in children with high negative affectivity or low approach.

Other Dimensions

A number of other traits have sometimes been classified as broad-level traits under some frameworks while in others they are a component of one of the three dimensions described above. Three of them are the following.

Social Affiliation. Although aspects of social affiliation can be subsumed under broad conceptualizations of extraversion, other researchers have viewed a person’s tendency toward prosocial behavior as a distinct higher-order trait. Elements of social affiliation are also found in terms such as shyness, although merging these concepts has been seen as problematic by some because it equates the *desire* for social contact with the anxiety or *discomfort* associated with social encounters. As an aspect of temperament, this dimension has been called sociability and reward dependence, among others, whereas under a personality "Big Five" taxonomy it is related to the trait of agreeableness. In some systems, this dimension encompasses elements such as empathy and the desire and ability to share emotional states with others, as well as with dependency and compassion.

Activity Level. A person's level of motor activity is similarly viewed as a component of extraversion in some models, whereas in others, such as that proposed by Buss and Plomin, it is given additional standing in itself. Its ability to be readily observed by others, genetic influence, and emergence as a distinguishing feature very early conform to some of the core requirements of a temperamental trait.

Behavioral Inhibition and Disinhibition. One well-studied temperament trait has been called behavioral inhibition (BI). It was defined by Harvard psychologist Jerome Kagan and colleagues to refer to a subgroup of young children (about 10% to 15% of the population) who consistently responded to new situations and people with reticence and fear. His research group later defined a group of children with the exact opposite response to novelty and referred to them as possessing behavioral disinhibition. Unlike the conceptualization of most temperament dimensions, BI has been studied primarily as a binary trait that a person either does or does not possess. As will be discussed in more detail, children who manifest BI as toddlers have been shown to be at risk for psychiatric disorders later in life, in particular social anxiety disorder.

Temperament Types

As mentioned, an alternative approach to understanding temperament focuses on distinguishing groups of individuals who may possess similar levels across a variety of traits. This emphasis on temperament types should not be considered to be a true substitute to a variable-centered focus but rather a complementary approach, in that these person-centered classifications also rely on specific dimensions to define various classes or types.

The Difficult Child. Probably the most famous temperamental type is the "difficult" child designation of Chess and Thomas, which was distinguished from the "easy" and "slow to warm up" groups (and from children who didn't fit any of the three types). The "difficult" category referred to a cluster of about 10% of young children who possessed the particular combination of low rhythmicity, low response threshold and adaptability, and high response intensity. Although not hypothesized to reflect psychopathology per se, it was this group of children in longitudinal studies who were most likely to have poor outcomes and greater psychiatric disturbance.

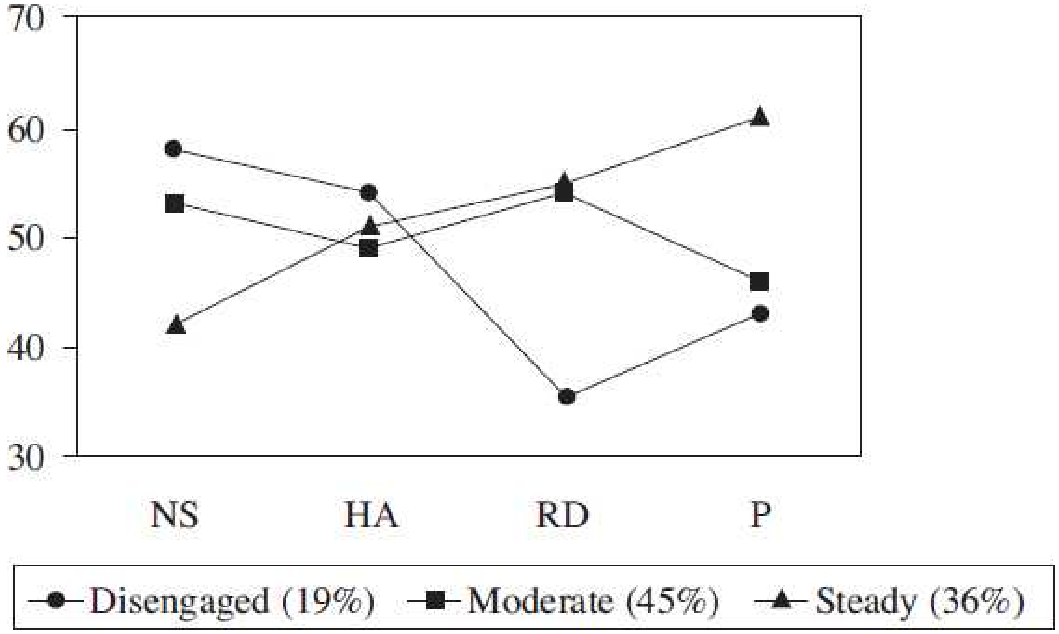


FIGURE 38–1. Temperament profiles as determined through latent profiles analysis. The "moderate" group has average levels across all dimensions, whereas the "steady" group is characterized by low novelty seeking (NS) and high persistence (P). The "disengaged" group has moderately high levels of both novelty seeking and harm avoidance (HA), with low levels of reward dependence (RD). The groups have been found to be related to levels of psychopathology and wellness. (Adapted from Rettew DC, Althoff RR, Dumenci L, Ayer L, Hudziak JJ. Latent profiles of temperament and their relations to psychopathology and wellness. *J Am Acad Child Adolesc Psychiatry.* 2008;47(3):273–281.)

New Approaches to Temperament Types. Statistical procedures such as cluster analyses and latent profile analysis can now be used empirically to identify groups of children who manifest similar levels of traits across several dimensions. These analyses can be performed without preconceived theories of how different traits *should* exist together. Studies that apply these kinds of analyses typically find evidence for a relatively small (often around three to six) number of groups distinguishable by their unique temperamental profile. In one study, latent profile analysis of a group of children of ages up to 18 years revealed the presence of three temperament types (Fig. 38–1). The first, as might be expected, contained people who did not have extreme levels of any dimension and was labeled the “moderate” group. A second group was characterized by low novelty seeking and high persistence and was named the “steady” group. Finally, the least common group contained those who possessed high novelty seeking, high harm avoidance, low persistence, and, most prominently, low reward dependence (low sociability and attachment to others). This last group was labeled the “disengaged” group. As will be discussed, these groups had strong associations with both positive and negative outcomes. Similar efforts by other investigators and using other samples have also tended to find evidence for a relatively small (often around 3 to 6) number of groups distinguishable by their unique temperamental profile.

FEATURES OF TEMPERAMENT

Temperamental traits can be observed in infancy and, according to some, even before birth. They have been observed across a wide number of cultures. Although temperament contributes to an individual’s unique human characteristics, these traits have been widely studied in animals ranging from nonhuman primates to dogs to guppies.

Sex Differences

A review and meta-analysis of sex differences using Cloninger’s temperament framework showed higher levels of reward dependence and harm avoidance in women than in men, whereas novelty seeking and persistence were found to be roughly equal. Of interest, another meta-analysis of child studies using Rothbart’s temperament structure found slightly different results with corresponding dimensions. Specifically, effortful control was found to be higher in girls, surgency was higher in boys, and negative affectivity was roughly equal. These results suggest the possibility that gender differences in temperament may be age-related. Overall, sex differences with many temperament dimensions can be found but are often smaller in magnitude than might be predicted from cultural stereotypes.

Continuity

By definition, temperamental traits are at least moderately stable across time, and most research supports this assertion. This quality does not mean, however, that a person's temperamental profile should be viewed as unchangeable or as someone's "destiny." Studies that measure how strongly a level of a temperament trait at one time point predicts the same trait in the future routinely find modest but statistically significant correlations even decades later. Longitudinal assessments of BI have shown that, while most children do not retain that designation years later, the presence of BI at follow-up can be predicted by initial BI status. In general, increasing stability of a temperament trait has been related to (1) higher baseline age of temperament assessment, (2) shorter time intervals between assessments, and (3) possessing more extreme levels of the trait.

An interesting offshoot of the temperament stability question relates to the possibility that physiologic "footprints" of traits persist even in the absence of observable behavior. In one study, adults who at the age of 2 years were classified as being behaviorally inhibited were scanned using functional magnetic resonance imaging (fMRI). When shown pictures of novel faces, the previously inhibited adults showed higher amygdalar activity than adults who were not inhibited as toddlers, despite the fact that these subjects did not report any increased anxiety. This intriguing result and others like it suggest the possibility that the physiology underlying a temperamental trait can linger despite an outward lack of the trait itself. One mechanism through which this may occur is that other brain areas and circuits, such as those involved in executive functioning, might mature with development and keep a person's behavior more regulated despite enduring internal feelings of discomfort.

Another type of stability, mean level stability, refers to the overall level of personality traits at one age compared to each other. This can be a difficult phenomenon to measure, especially in childhood and adolescence due to the fact that what behaviors constitute a particular trait can change across development. These challenges notwithstanding, there is evidence that across children and adolescents, different traits have different trajectories over time and may even vary between girls and boys. Levels of extraversion, for example, have been shown to dip somewhat in midadolescence before climbing in late adolescence and early adulthood.

NEUROBIOLOGY AND ETIOLOGY

There has been an explosion of research into the neurobiologic underpinnings of temperament and personality. Although a thorough review of this literature is beyond the scope of this chapter, many important findings are particularly relevant for understanding the boundaries and interplay between temperament and psychopathology. For many years, research on the neurobiology of psychiatric disorders existed in parallel with similar efforts in temperament and personality. As these independent efforts began to reveal similar findings, however, there have been increased efforts to assess temperament and psychopathology concurrently.

Genetic Influences

The genetic influence on temperamental traits has been well established through a large number of behavioral and molecular genetic studies. Twin and adoption studies across all ages have generally shown that genetic factors explain about 20% to 60% of the variability in temperament scores within study populations, depending on age and the particular dimension being examined. These heritability coefficients tend to be highest in twin studies when temperament is assessed by a questionnaire completed by a single informant (such as a parent rating both twins) and lower in adoption designs or studies that measure temperament using observational protocols. Furthermore, this genetic influence has often been found to be mainly of the additive type, in which multiple genes exert small, independent effects. Nonadditive genetic influence, such as in genetic dominance or epistasis, have also been found to a lesser degree in some studies. Although most studies usually do not find major sex differences in the *magnitude* of genetic factors, it is not uncommon to find evidence that different genes contribute to particular dimensions between males and females. One somewhat counterintuitive finding that has emerged in some studies is that the heritability of some traits appears to be fairly low in the neonatal and early infancy period—a time in which some might expect to find the largest genetic influence—and then grow over time. These findings lead to the conclusion that environmental factors can play important roles even in infancy, and new genetic and environmental factors come online to contribute to both temperament stability and change across development. These results are reflected in many anecdotal reports of parents who marvel at how different their children's temperaments are from each other despite the children sharing half of their genes and being raised in the same household. Indeed, studies have documented only modest correlations between siblings. Although statistically significant, the moderate level of temperamental differences between siblings suggests that the effects of genetic factors are limited and that individual environmental experiences may play a large role in shaping traits over time.

The question of exactly *which* genes contribute to a particular trait is left for molecular genetic studies that attempt to link temperamental traits to chromosomal regions or known alleles of specific genes. While the validity of older candidate gene studies has more recently been questioned, genome-wide association studies continue to be performed and yield positive results, with some recent efforts showing temperament related to single nucleotide polymorphisms (SNPs) in a number of genes involved in synaptic plasticity, learning, and stress reactivity.

Environmental Factors

As mentioned, the other major source of influence for temperamental traits comes from environmental factors. These experiences have been documented to have stronger influences on temperament than many have assumed. From a behavioral genetic perspective, environmental factors come in two main types. The first are those events that have a similar effect on all members of a family and are called shared or common environmental events. Socioeconomic status, parenting practices, and school quality are all potential shared environmental factors to the degree that their effect on siblings in a family is equal and in the same direction. Nonshared environmental factors, by contrast, are environmental events that are not shared by members of the same family and can contribute to making siblings different from each other. Examples here could include a child's peer group or a powerful positive or adverse experience.

Many of the same twin and adoption studies that have shown evidence for genetic influence also show unequivocal evidence for environmental influence, particularly of the unshared type. At the same time, there has been much less support for robust shared environmental effects. This pattern does not necessarily mean that things such as parenting or poverty are unimportant, but rather that they may not affect people as uniformly as was once hypothesized.

Genetic–Environmental Interplay

The old nature-versus-nurture debates assumed that genetic and environmental effects work through mutually exclusive pathways. A child inherits a particular gene or experiences a certain event, and those factors affect behavior directly. More recently, however, it has become increasingly appreciated that genes and environments have bidirectional influences. Environmental events can control gene expression. Conversely, genetically influenced tendencies can cause certain environments to be more likely to occur (gene–environment correlations), and those environments can, in turn, affect behavior. Finally, the effect of a particular gene can depend on the presence of a particular environment and vice versa (gene–environment interactions). Understanding these complex relations has become a major focus of neuroscience research and has brought with it a new perspective on human development that crosses old boundaries.

Neurotransmitters and Brain Circuitry

Whether behavioral influences are genetic, environmental, or an intricate combination of the two, their ultimate effect is to shape specific brain regions and their connections to other areas. Advances in the knowledge of brain function and its plasticity from environmental factors are rapidly rendering obsolete terms such as “biologic” or “organic” to describe some behaviors but not others. Nevertheless, there is still much to learn about the specific pathways and neurochemical substrates involved in temperament. Many of the specifics remain unknown, and current models and explanations are acknowledged to be vast oversimplifications.

The trait of negative affectivity and related terms such as harm avoidance and BI have often focused on the amygdala and its multiple afferent and efferent pathways. In a study combining genetic and neuroimaging techniques, researchers found significant associations between reduced amygdala/anterior cingulate connectivity and higher levels of harm avoidance. Amygdalar hyperreactivity has also been postulated to be one of the core features underlying the trait of BI.

Ascending pathways from the reticular activating system to the medial septal area and modulated by the orbital frontal cortex have also been related to passive avoidance and behavioral extinction. Related to these functions, dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis has also been found to be associated with this dimension.

Animal studies have implicated ascending serotoninergic pathways from the dorsal raphe to the basal ganglia, substantia nigra, nucleus accumbens, and amygdala. These pathways can be modulated by γ-aminobutyric acid (GABA), as well as by dopaminergic pathways from nigrostriatal regions. Dopamine pathways have frequently been found to play an important role in the approach behavior and spontaneous activity related to the trait of novelty seeking or extraversion. The mutually interacting systems of harm avoidance and novelty seeking may be related to the typical negative correlation between these two traits. Some brain laterality has also been reported in EEG studies, with left frontal activation being related to more positive emotions and approach, and right frontal activation being related to more negative emotions and withdrawal.

Social affiliation and related traits such as reward dependence are hypothesized to be related to noradrenergic pathways from the locus ceruleus, as well as serotoninergic projections from the median raphe, which innervate a number of areas in the cortex, thalamus, and hippocampus. Neuroactive hormones such as oxytocin may also play important roles in social behavior, as illustrated by the marked behavioral differences between two species of voles that correspond to alterations in the distribution of oxytocin receptors in brain reward centers. Dimensions such as persistence or effortful control are thought to be mediated through many areas of the anterior cortex that modify the function of subcortical regions. Many of these pathways also involve dopaminergic transmission. As previously described, the anterior cingulate gyrus is connected both to limbic structures such as the amygdala and to areas of the lateral cortex, thereby providing a link between key emotion processing and executive function regions.

In describing the genes, neurotransmitters, and neuropathways related to temperament, it becomes quickly apparent that the discussion involves all of the “usual suspects” in psychiatric illness. Realization of this repeated finding has prompted systematic efforts to delineate the boundaries between temperamental traits and psychiatric illness in the hope of identifying potential targets of therapeutic intervention.

TEMPERAMENT AND PSYCHOPATHOLOGY

Despite the current conceptualization of psychiatric illness in DSM-5 as binary entities that exist in all-or-none form, there is now overwhelming evidence that almost all symptoms of psychopathology exist on a continuum. This spectrum ranges from a large segment of the population who present with few or no difficulties in a particular area to a gradually diminishing number of individuals with higher degrees of symptomatology and finally to a small number of people with extreme levels. Having both a quantitative and dichotomous perspective on a particular disease is not unique to psychiatry. Although all people have a measurable blood pressure, for example, individuals with a pressure greater than 140/90 mm Hg are considered to have the diagnosis of hypertension.

As the dimensional aspects of psychiatric disorders have become increasingly appreciated and measured, it is not surprising that people have begun to hypothesize that temperament or personality dimensions may underlie this wide distribution of symptom severity. This realization may have been somewhat inevitable, given hypothesized temperament dimensions such as mood, activity level, and attention span, all of which have descriptive similarities to specific psychiatric conditions. Indeed, when the range of psychiatric instruments is extended to include those on the opposite end of the spectrum (e.g., going beyond the distinction between children with attention problems and no attention problems to include those with excellent abilities), the distribution of the scores begins to approximate the bell-shaped curve of many temperament traits. This understanding has led to the speculation that what is currently classified as psychiatric disease may actually represent the extreme tail of normally distributed traits that exist in the entire population.

Table 38–4.
Possible Mechanisms of Temperament/Psychopathology Associations

Model	Description	Example
Spectrum/continuum	Most psychiatric disorders are best conceptualized as existing on a continuum with temperament or personality traits.	Activity level is a temperamental trait, and people with attention-deficit/hyperactivity disorder are at the end of that spectrum.
Risk/vulnerability	Temperament is different from psychopathology but can increase the risk of its occurrence.	People with high levels of novelty seeking are at increased risk for substance abuse.
Common factor	Temperament and psychopathology share common etiologic factors, which are then acted on by other factors that lead some people to develop a disorder.	People with posttraumatic stress disorder share similar genes with temperamentally anxious people but have experienced severe trauma.
Pathoplastic	Temperament and psychopathology are unique but have bidirectional influences on each other.	The long-term prognosis of depression is better for individuals with high effortful control.
Scar	The pathophysiology of psychiatric disorders can alter temperament.	The plaques and tangles associated with Alzheimer disease cause personality changes that are observed prior to other symptoms.

To distinguish “true” psychiatric illness from subthreshold or developmentally expected levels of behavior, clinical teaching has dictated that one of the most important considerations is *impairment*, that is, whether the behaviors, thoughts, or emotions interfere with a person’s daily life and functioning. While this convention is theoretically appealing, research has demonstrated that impairment itself also tends to exist along a continuum. People who are severely depressed, for example, are quite impaired, whereas those who are a little depressed are somewhat impaired, and so on, with no convenient cut-off. Complicating matters further in the field of child psychiatry is the fact that impairment is often not defined by the child but rather by caregivers, who may differ in their definition of impairment based on their own strengths, weaknesses, and expectations.

As psychiatry continues to demonstrate these strong associations between temperament and psychopathology, several mechanistic hypotheses have been proposed to explain this link. These models are summarized in Table 38–4.

The two most investigated potential mechanisms have been described as the *spectrum model* and the *risk or vulnerability model*. The spectrum perspective, as previously mentioned, postulates that psychiatric symptoms and temperament dimensions lie on a common continuum with no clear qualitative distinctions. The difference between a trait and a disorder, therefore, is simply a matter of degree or magnitude. Implicit in this theory is that there also is common underlying neurobiology between temperament and psychopathology. The factors that determine a child’s level of normal developing activity, for example, are the same as those that underlie another child with hyperactivity, albeit perhaps more amplified.

The risk or vulnerability model of temperament/psychopathology relations considers temperamental traits and psychiatric disorders to be qualitatively different entities but with temperament acting as a risk or protective factor for future development. Although it is easy to differentiate conceptually between a risk factor such as sunlight exposure and a disease such as melanoma, the description of something like shyness being a risk factor for social anxiety disorder lacks these salient points of obvious divergence. Proponents of this mechanism, however, point out that there are many examples of normally distributed variables that mask a number of very different underlying processes. Intelligence quotient, for example, often shows a normal distribution in large samples. To assume, however, that there is a common quantitative mechanism underlying this distribution would miss, among other things, the small numbers of individuals whose score is related to a distinct and qualitatively different mechanism, such as the trisomy of chromosome 21 that leads to Down syndrome. In addition, there is also a hybrid of the spectrum and risk models that proposes true phenotypic differences between temperament and psychopathology but some common underlying features, such as shared genetics, that are then acted on by other factors, such as specific adverse or positive experiences to create important points of divergence.

These three models tend to be the most dominant in the literature when it comes to temperament/psychopathology interactions. However, two other models, both of which preserve the uniqueness of pathophysiologic processes, deserve mention. In the pathoplastic model, temperament and psychopathology are distinct but can mutually influence one another. Temperament can increase the chance that a child will suffer a major depression, for example, and that depressive episode can, in turn, exert effects on the child's personality going forward. Finally, the "scar effect," in many ways the reverse of the risk model, proposes that it is the pathophysiologic mechanisms that underlie psychiatric disorders that then modify one's personality. An example of this effect may be Alzheimer disease. Although personality change is common with this condition and often precedes more specific Alzheimer symptoms, it is thought that the early-developing pathology of plaques and tangles affects personality, rather than the other way around.

Scientists have thus turned to modern research designs and tools to help disentangle these complex relations among temperament, personality, and psychopathology. In so doing, there has been a realization that what were previously thought to be clear boundaries might be much more muddled. What appears to be a continuous trait, like intelligence, may develop from a number of small, discrete causes. Conversely, what appears to be a binary yes/no illness might have more embedded gradations when examined closely. In Huntington disease, for example, the number of trinucleotide repeats in the huntingtin gene affects the onset and course of illness. It is also important to keep in mind that the various mechanisms are not mutually exclusive. Within a particular trait–disorder pair, there may not be a single mechanism at work across different individuals and perhaps even within individuals. Some individuals with obsessive-compulsive disorder may have strong temperamental correlates, whereas the symptoms of other individuals might be the result of an autoimmune process.

As is clear from these examples, improved understanding of the way illness is conceptualized has important clinical implications. From a research standpoint, it is vital to ensure that any boundaries, should they exist, between temperamental traits and psychiatric illness be delineated because all results downstream of that categorization are likely to be affected. If children who just barely meet DSM-defined attention-deficit/hyperactivity disorder (ADHD) have a brain physiology that is nearly identical to children who just miss the diagnoses, then using the latter group as controls in an fMRI study, despite their lack of diagnosis, is unlikely to yield fruitful results. Thus, the next section is devoted to describing the current state of knowledge with regard to the existence and mechanism of temperament/psychopathology relations (Table 38–5).

Table 38–5.
Associations Between Temperament Traits and Various Categories of Psychiatric Disorders

	Negative Affectivity	Extraversion	Effortful Control
Attention-deficit/hyperactivity disorder	High	High	Low
Other disruptive behavior disorders	High or low	High	Low
Major depression	High	Low	Low
Anxiety disorders	High	Low	Low
Substance use	High	High	Low
Autism	High	Low	Low
Eating disorders	High	—	High (anorexia) or low (bulimia)

Adapted from Rettew DC. *Child Temperament: New Thinking About the Boundary Between Traits and Illness*. W. W. Norton & Company; 2013.

ADHD and Disruptive Behavior Disorders

ADHD is a prime example of a disorder that, at least phenotypically, appears to be conceptualized as the upward range of a continuum defined by temperamental traits related to activity level and attention span. Indeed, much of the public controversy surrounding this diagnosis is related to the perception that what is being diagnosed as illness is normal temperament, albeit at somewhat higher levels than are typically observed. As might be expected, low levels of effortful control and persistence have been found, in addition to higher levels of novelty seeking and extraversion, especially among children who meet the criteria for the hyperactive-impulsive or combined subtype of ADHD. A study of 8,500 twin pairs found evidence for a continuum model of ADHD with nearly identical heritability estimates (around 0.60) for those with diagnostic versus subthreshold levels of behaviors. Another study subtyped a group of children with ADHD according to temperament and identified three groups that they labeled mild, surgent (with high levels of approach behavior), and irritable (with higher emotionality and poorer regulatory skills). These temperament-based groups, compared to traditional DSM-based presentations, were shown to provide better cohesion with regard to stability over time, functional brain connectivity, and cardiac physiologic parameters.

Other disruptive or externalizing disorders include oppositional defiant disorder (ODD), conduct disorder, and, in adults, antisocial personality disorder. All of these entities are rather heterogeneous, making the task of linking specific temperamental traits with these disorders difficult. Aggression, for example, is often divided into more instrumental and reactive subtypes. In the former, sometimes known as type 1 psychopathy, aggressive acts can be planned in advance and without provocation. These behaviors are often associated with individuals who tend to lack empathy and possess what are termed callous and unemotional traits, now incorporated into the conduct disorder diagnosis in DSM-5. Physiologically, many of these individuals have been shown to have an underaroused autonomic nervous system that craves additional stimulation. In reactive or type 2 psychopathy, individuals quickly perceive threat from others and have difficulty modulating their emotional responses. This latter type is more strongly linked to deficits in emotional regulation, as well as to increased negative affectivity. Oppositionality has similarly been found to break into three dimensions, labeled irritable, headstrong, and hurtful. These dimensions show different comorbidity patterns with regard to other DSM disorders.

Mood and Anxiety Disorders

Often collectively referred to as internalizing disorders, mood and anxiety disorders are some of the most common psychiatric conditions in childhood and adolescence. Although they are considered to be separate categories of illness according to current clinical nomenclature, there is good empirical evidence to support their being closely linked. Consistent with this hypothesis is the finding of similar temperamental correlates common to both mood and anxiety disorders. By far the strongest association is with the dimension referred to as negative affectivity, neuroticism, or harm avoidance. Major depression has also been associated with the combination of high negative affectivity and low approach. Bipolar disorder, especially the purported “broad” phenotype now often diagnosed as disruptive mood dysregulation disorder and characterized by nonepisodic irritability and explosiveness, has been shown to be related to a somewhat unique temperamental combination of high novelty seeking *and* high harm avoidance. This “approach plus avoidance” pattern stands in contrast to the general tendency of novelty seeking and harm avoidance being inversely related to each other.

More generalized and chronic internalizing disorders such as generalized anxiety disorder (GAD), dysthymia, and social anxiety disorder have been hypothesized as the high end of a spectrum of negative affectivity and/or low extraversion. Direct analyses of this hypothesis, however, suggest that such a model is oversimplified. As shown in Figure 38–2, many people who possess even very high levels of harm avoidance do not meet the criteria for GAD, whereas some individuals with moderate levels of harm avoidance do. On the genotype level, behavioral genetic studies indicate that approximately half of the genes that contribute to neuroticism are the same genes that contribute to internalizing disorders, whereas half do not. Thus, despite the obvious content overlap between descriptions of anxious temperament and descriptions of anxiety and depressive disorders, the majority of evidence appears to point to temperament dimensions having more complex relations with these disorders rather than simply being a different point along a continuum, especially of a single temperament trait. The cyclic and episodic nature of other types of mood disorders, such as recurrent major depression or panic disorder, further suggests that elements other than temperament need to be incorporated into the current theoretical models.

Low effortful control or persistence has also been associated with internalizing disorders. Indeed, temperamental dimensions relating to regulatory control appear to be a common correlate to most psychiatric disorders, with other dimensions related more to the specific *type* of psychopathology. As mentioned, the construct of BI developed by Kagan and colleagues likely combines elements of high negative affectivity, low approach, or surgency, and perhaps low effortful control. Longitudinally, however, the strongest association found has been between BI and generalized social anxiety disorder with a meta-analysis revealing that 43% of young BI children meeting the criteria for social anxiety disorder later in development.

Autistic Spectrum Disorder

To many clinicians observing a nonverbal child with stereotypical behaviors, autism would seem to be a condition that is more binary in nature. However, as the name suggests, accumulating evidence has demonstrated that many of the core symptom clusters of autism, such as social cognition, communication, and affiliation, as well as the stereotypical behaviors themselves, exist along a continuum when measured quantitatively. Temperament dimensions such as low sociability or reward dependence, high negative affectivity, and low extraversion have all been associated with autism. At the same time, it is important to remember that the finding of a continuous distribution of phenotypic behaviors does not prove that a common neurobiologic mechanism underlies the entire spectrum. Indeed, studies showing focal areas of cytoarchitectural disorganization in the neocortex of individuals with autism suggest that, at least for some individuals, a “scar” mechanism may be at work in which the pathophysiology of the disorder drives the temperamental differences that are also observed. There is some additional support for the possibility that qualitative differences in brain structure and function exist between individuals who meet the criteria for autism and those who possess some of the same traits (albeit at lower levels) from the neuroimaging literature, although much more work is needed to explore this intriguing hypothesis.

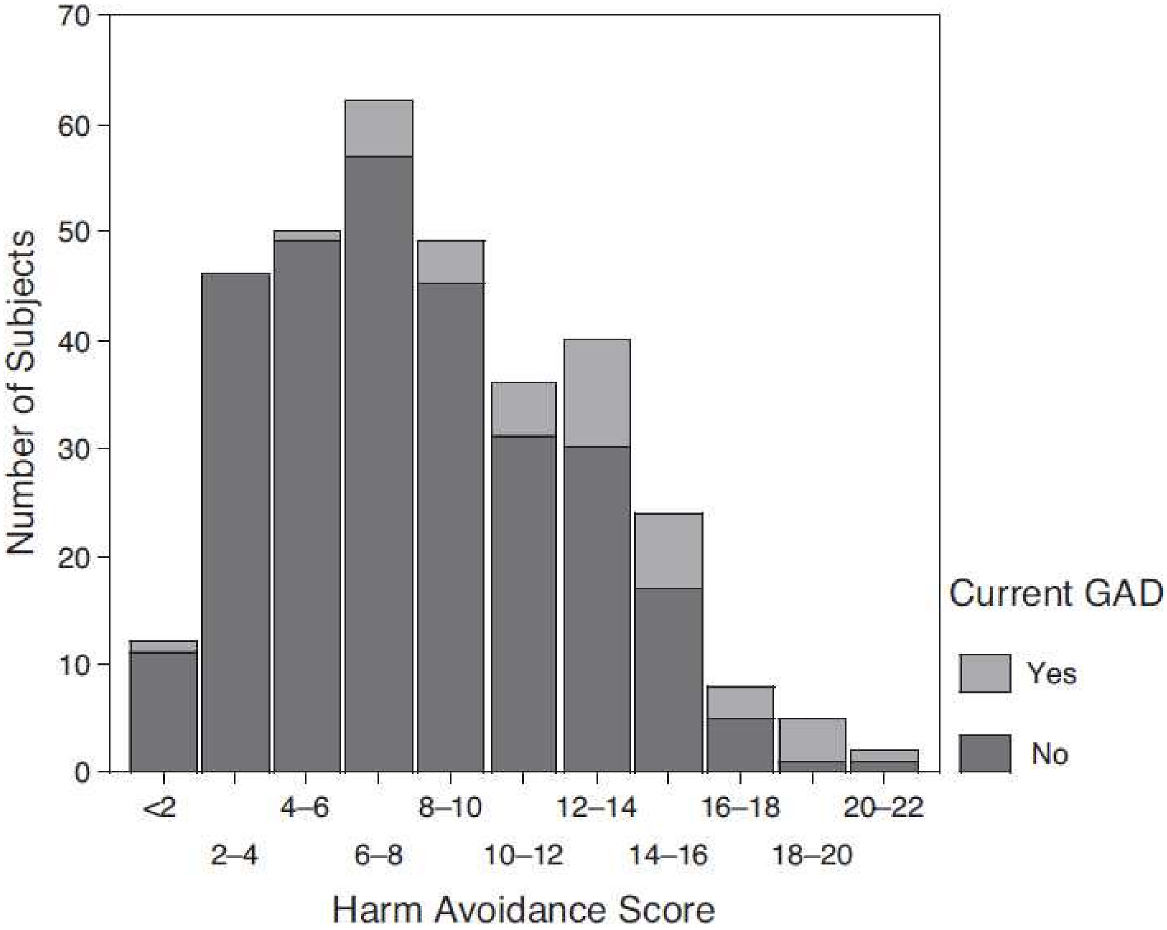

FIGURE 38–2. Distribution of harm avoidance (HA) scores in children and adolescence. Subjects whose results are given also have generalized anxiety disorder (GAD), according to the criteria of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). The pattern reveals substantial but not complete overlap between harm avoidance and GAD, with a few subjects with high HA without GAD, some individuals with moderate HA with GAD, and very few individuals with low HA with GAD. (Reprinted from Rettew DC, Doyle AC, Kwan M, Stanger C, Hudziak JJ. Exploring the boundary between temperament and generalized anxiety disorder: a receiver operating characteristic analysis. *J Anxiety Disord.* 2006;20(7):931–945. doi:10.1016/j.janxdis.2006.02.002.)

Other Disorders

Some types of disorders are defined by behaviors that are conceptually more distinct from core temperamental traits and thus do not lend themselves as easily to spectrum hypotheses. Discrete actions such as binging and purging in eating disorders, hallucinations in psychotic disorders, and the taking of illicit drugs in substance use disorders may fall into this area. Many of these entities also tend to have onsets in adolescence or later and thus have most of the research directed at personality traits rather than temperament per se.

In substance use disorders, the choice of substances that is used, each with unique physiologic effects, might be partially related to an individual's unique temperamental profiles. Different agents also vary in their legality, which itself could lead to unique associations with particular traits. Alcohol use, for example, is legal for adults but not children and thus may have different temperamental associations by age. One follow-up study of temperament found indications that adult alcohol abuse was associated with being both temperamentally undercontrolled and overcontrolled as a child. Novelty or sensation seeking, especially when defined apart from positive emotionality, has also been associated with increased substance use. Once again, dimensions such as effortful control are related to lower amounts of substance use disorders. An interesting caveat in personality research in substance use acknowledges the shifting cultural perceptions of particular substances over time. Cigarette use, for example, has become viewed as increasingly deviant over the last 50 years across many segments of Western culture. One might expect, consequently, that its use is less associated with traits such as agreeableness over time or compared to cultures in which its acceptance level is greater.

Whereas most individuals with eating disorders regardless of specific diagnosis share a preoccupation with weight and self-image, there also appear to be substantial differences that generally fall along diagnostic lines, particularly between the restricting subtype of anorexia nervosa (AN) and bulimia nervosa (BN), and these may reflect underlying differences in temperament and personality. In particular, low effortful control and persistence has been found with BN but not in AN, where effortful control can be higher than controls. High neuroticism or harm avoidance has also been found for both disorders and parallels the frequent finding of anxiety disorders that can co-occur or precede eating disorders.

Temperamental associations with psychotic disorders have been less studied, although parallels especially with the negative symptoms of schizophrenia would appear to be fertile ground for investigation. High harm avoidance has been found in both patients with schizophrenia and their relatives, whereas high novelty seeking may be associated with more violent behavior. While positive symptoms such as hallucinations might be assumed to be relatively rare in the population and be present in more of an all-or-none form, recent research has suggested that lower-level forms of psychotic thinking are more prevalent than previously thought.

A Case Example

Previous “diathesis–stress” models of psychopathology that include temperament often frame temperamental traits as the diathesis component, which is then acted upon by various stressors, such as parenting behavior, traumatic events, and other factors to produce psychiatric symptoms. While data described in this chapter reveal that such a model is likely overly simplistic when it comes to how temperament is conceptualized, certain aspects of this model can still be useful. One of the principal advances from older conceptualizations of the diathesis–stress model is the full appreciation that the stressors often do not act on the diathesis randomly but rather are probabilistically more likely to occur because of those predispositions. As previously discussed in the section on temperament development, these processes have been called genotype–environment correlations and are readily applicable to the understanding of how risk factors like certain temperamental traits contribute toward the creation of environments such as parental behaviors and peer groups that accentuate those initial predispositions. A case example may illustrate this mechanism best.

Kayla was a child who from birth appeared to be more fearful and easily upset than other infants. She cried frequently and forcefully, and as a toddler, she was more reluctant to leave her mother's side to play with other children and to explore new situations. Her behavior was a challenge to her mother, who herself struggled with significant anxiety and shyness. As a result, her mother was not prone to seek out activities such as play dates with other parents, and when she did, Kayla's behavior made them frequently go badly. Hoping to avoid another embarrassing scene, Kayla's mother became increasingly overprotective in her efforts to shield her daughter from situations that might provoke discomfort. By the time kindergarten started, Kayla had had significantly fewer opportunities to interact with other children and tended to keep to herself. Throughout elementary school, she avoided team sports and other structured social activities, preferring other activities such as learning to play the piano. She did manage to make some lasting friendships, although they tended to be with other children who were also quiet and reserved. Kayla became an easy target of teasing by others, and as an adolescent, she became increasingly self-critical about her demeanor. At the age of 14 years, she saw a psychiatrist for the first time and was diagnosed with social anxiety disorder and major depression.

This illustration demonstrates how insidious the progression can be from temperamental traits to psychiatric disorders and how difficult it can be to ascribe the causation of symptoms as purely genetic or environmental. The case also illustrates the role of other factors in shaping a temperamental trajectory toward more maladaptive outcomes.

OTHER CONCEPTS IN TEMPERAMENT–PSYCHOPATHOLOGY RELATIONS

Parenting Behavior

The fact that some parenting behavior is evoked by children does not mean that parenting is either unimportant or inevitable. Neither does it mean that suboptimal parenting is the fault of the children. Rather, a more transactional view appreciates the bidirectional influences of children and parents that together can create important home environments with important developmental effects. Research has shown, for example, that parents of anxious children are more likely to teach avoidant rather than prosocial solutions to problems and may facilitate the perception of threat in ambiguous situations. As shown in the case example, these parents can become overprotective, which limits the crucial exposure opportunities that can help children to overcome their anxieties. Lack of parental warmth, poor supervision, harsh and inconsistent discipline, and obviously abuse are all important parental behaviors that have been found to be related to various types of psychopathology and serve as critical intermediaries between temperament and psychopathology. An important meta-analysis from 2016 demonstrated the somewhat counterintuitive finding that children with “difficult” temperaments were more sensitive to parenting influences “for better or for worse,” meaning that they benefited more from positive parenting and were more vulnerable to negative parenting than those with other temperament profiles.

Cognitive Factors

Although some cognitively-related attributes, such as attentional skills, are often included under the temperament umbrella, other aspects, such as intelligence, processing speed, and memory, are generally considered outside of the temperament domain. Nevertheless, these cognitive processes likely also play important moderating roles. Children with relatively diminished attention spans but above-average intelligence, for example, may be able to use that intellectual ability to counteract their attention deficits and prevent the clear impairment required for a diagnosis of ADHD. Other cognitive functions, such as the attributional style that a person applies to interpret themselves and the world around them, also likely shape and are shaped by temperament. These types of appraisals and attributions have been found to be important in a variety of both internalizing and externalizing disorders.

Trauma and Adverse Events

Clearly, both single-episode traumas, such as natural disasters and car accidents, and more chronic stressors, such as forms of abuse and poverty, can propel temperamentally at-risk children toward full-blown psychiatric symptoms. At the same time, it is becoming increasingly clear that one of the strongest predictors of more severe symptoms after a stressful event is poorer functioning prior to that event. Thus, a temperamentally aggressive child might be more likely to develop antisocial behaviors in the face of significant stressors, and a more anxious child might develop posttraumatic stress disorder after a single traumatic event.

Peer Groups and Activities

A powerful behavioral influence, especially for older children and adolescents, is a child's peers and the shared experiences that are done together. Similar to parenting behaviors, it is very likely that peer groups have a bidirectional influence on temperament and personality traits. A high-novelty–seeking child, for example, is likely to have similar-minded friends who may push each other to ever riskier and more dangerous activities. These group experiences provide opportunities both to magnify more maladaptive behaviors and to channel temperamental tendencies productively. Research has shown, for example, that adolescents on sports teams are less likely to smoke cigarettes. Given that participation in sports teams appears to have its strongest environmental influence early in life, a possible intervention target emerges for future research.

Temperament and Resiliency

Just as some temperamental traits can mix with the aforementioned variables to generate negative momentum toward psychopathology, other traits can serve as protective factors in the face of adversity and, indeed, may be important not only for a lack of psychopathology but also for true mental health and wellness. The previously mentioned study using latent profiles analysis found that compared to a group of children with moderate levels of most temperament traits, the "steady" group, characterized by high levels of persistence and low levels of novelty seeking, performed better at school by parent and teacher report, engaged in more activities, and functioned better socially. Just like at-risk traits, these dimensions are likely operating with a number of other factors through the same mechanisms of gene–environment correlations and interactions. The Project Competence study, which followed children into adulthood, found robust predictions between child temperament/personality and adult functioning even after controlling for a number of baseline and demographic characteristics.

Goodness of Fit

Although it is easy to slip into the notion that some temperament traits are good and others are bad, it is important to remember that all traits possess both positive and negative qualities. High novelty seeking, for example, generally contains positive elements of being energetic and spontaneous in addition to being prone toward extravagance and impulsivity. Thomas and Chess popularized the notion of goodness of fit decades ago, and it remains a cornerstone of child development theory. Simply put, the idea behind goodness of fit is that particular temperamental traits are not positive or negative per se but become so in an environmental context. A fearful temperament, for example, might be very adaptive in more dangerous settings but becomes less useful when the environment is safer and more predictable.

Research in animals and humans has supported this important hypothesis, although not necessarily at extreme levels. In a study by Rettew and colleagues, certain child temperament traits were related to behavior problems only in the presence of certain parental traits (Fig. 38–3). High child novelty seeking, for example, showed no relation to attention problems in families with a low-novelty–seeking mother but did show a high degree of attention problems when paired with a high-novelty–seeking mother.

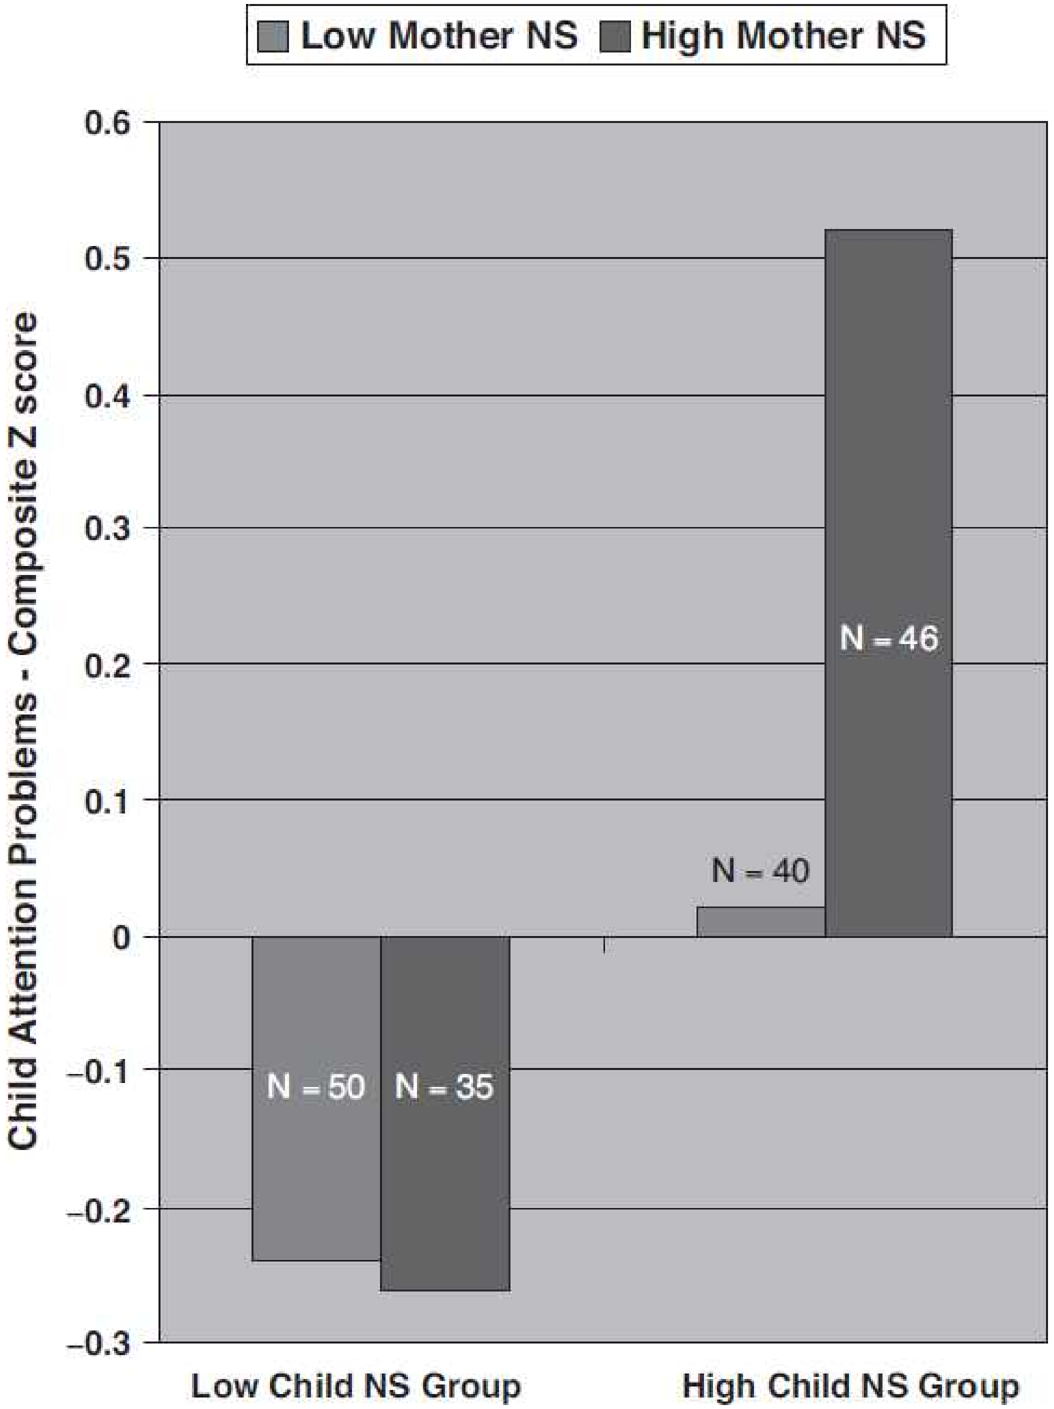

FIGURE 38–3. Relations between child and mother novelty seeking (NS) and attention problems. Children with low NS show few attention problems regardless of maternal NS. In high-NS children, however, a higher degree of attention problems is found in families with a high-NS mother but not in families with a low-NS mother. Results support the construct of goodness of fit in temperament/psychopathology associations. (Reprinted from Rettew DC, Stanger C, McKee L, Doyle A, Hudziak JJ. Interactions between child and

parent temperament and child behavior problems. *Compr Psychiatry*. 2006;47(5):412–420. doi:10.1016/j.comppsych.2005.12.008.)

CLINICAL IMPLICATIONS

It is clear at this point that the benefits of improved understanding regarding precisely how temperamental predispositions push children toward or away from more pathologic outcomes have much more than academic implications and may guide major efforts in early identification and intervention. If negative cycles of genetic–environmental interplay leading to disabling symptoms can be identified, they potentially can be stopped, perhaps even reversed. At the same time, more positive cycles can be cultivated and encouraged. Returning to the case example may be worthwhile.

After diagnosing Kayla with major depression and social anxiety disorder, her psychiatrist recommended cognitive–behavioral therapy to help Kayla overcome her dysfunctional beliefs and provide motivation for her to learn and apply new skills. The clinician also recognized similar symptoms in Kayla's mother and recommended a psychiatric evaluation, which resulted in her being prescribed a selective serotonin reuptake inhibitor (SSRI) and receiving individual treatment. Over time, Kayla learned to identify and challenge many of the negative thoughts that surrounded her behavior. Through the use of incentives, she was able to take small risks in approaching others socially. Her therapist recommended that she use her musical skills to her advantage, such as using her piano playing as a means to get out into public and receive positive social rewards. Her initial gains propelled her to take additional risks, and she joined the school orchestra. Meanwhile, her mother found that the decrease in her own anxiety allowed her to implement the therapist's suggestions more easily. Although Kayla never became a social butterfly, her depressive symptoms resolved, and she graduated from high school with confidence in her abilities and comfort with who she was.

Clinically oriented scientists are working hard to harness the energy that causes temperamentally predisposed tendencies to snowball into full-blown psychiatric syndromes and create pathways that not only will lead out of pathology but also into wellness. Given the complexity of these interactions, it is exceedingly likely that the specific relations between a particular trait and a particular disorder will vary considerably among individuals. Nevertheless, there is a tremendous promise that further study of temperament will not only dramatically alter some of the fundamental definitions of psychiatric disorders but also illuminate mechanisms that can improve the lives of children.

Intellectual Disability

EVAN TANIGUCHI, M.D., SOO-JEONG KIM, M.D., AND KAREN E. TOTH, PH.D.

HISTORICAL OVERVIEW

The field of developmental disabilities has wrestled with how to capture the condition now referred to as “intellectual disability” or “intellectual developmental disorder,” and has worked hard to encourage “people first” language. Individuals should not be defined by their illnesses or conditions—for example, John is not a “leper,” or a “schizophrenic,” or “autistic.” Instead, people *have* illnesses or conditions—for example, John *has* schizophrenia. Sensitivity around labels such as “low functioning” and “high functioning” has also grown. Although these lexical and grammatical sensitivities may seem trivial for some, there is no faster way to lose credibility in some settings than to characterize one’s patient as “low functioning.” Why such heightened sensitivity in this field? While it is well recognized that intellectual gifts have been distributed on a continuum for as long as mankind has walked the earth, the understanding and treatment of persons with intellectual disability (ID) has moved like a pendulum between extremes. At one end, persons with ID have been exalted, and considered “Les enfants du Bon Dieu” (“children of the Good God”). Certain media may convey the message that persons with intellectual or developmental disability are somehow blessed with simpler, more straightforward understandings of basic human truths. And at the other end of the pendulum swing, such persons have also been vilified. The word “cretin” (congenital hypothyroidism), takes its origin from “Christian or Christlike,” even as its modern dictionary definition includes descriptors like “stupid, vulgar, and insensitive.” In the introduction to his text on “mental defectives” over a century ago, Barr (1904), the chief physician at the Pennsylvania training school for the feeble-minded, observed that:

> “The terms idiot and imbecile indiscriminately applied for centuries to a despised and neglected class, have naturally, through the mere force of association, become synonymous with and even expressive of opprobrium and reproach. So closely welded has been this association of word and idea, that even the advance of the nineteenth century with all its revelation of true conditions has failed to sunder them.” (p. 17)

Evidence for the recognition and treatment of ID dates to the earliest medical writings. Hippocrates described microcephaly and craniostenosis, and Galen actively explored the causes of cognitive disability. In the Middle Ages, Avicenna proposed treatments for meningitis and hydrocephalus and even defined levels of intellectual function. Esquirol (1838) is credited as the first medical writer to define the disorder of ID and was careful to distinguish ID from mental illness or disease. He focused on congenital onset in noting that:

> “Idiocy is not a disease, but a condition in which the intellectual faculties are never manifested; or have never been developed sufficiently to enable the idiot to acquire such an amount of knowledge as persons of his own age, and placed in similar circumstances with himself, are capable of receiving. Idiocy commences with life, or at that age which precedes the development of the intellectual and effective faculties, which are from the first what they are doomed to be during the whole period of existence.”

Modern history in the field of ID begins in the late 18th and early 19th centuries. At that time, Jean-Marc Itard attempted a natural experiment to educate Victor, a “wild-child” discovered in the forests of Aveyron, France. Although Itard himself judged his work with Victor a failure, this famous experiment marked the important consideration that persons with disabilities might be educable. Itard's efforts generated interest in educational and other interventions for persons with disabilities. In some ways, Itard and those that followed provided a bridge from beliefs that individuals with ID were subhuman (even suggested by Linnaeus to be a separate species in the genus Homo with names like Juvenis Lupinus Hessensis—a young man found in Hesse among wolves, or Juvenis Hannoverianus—a young man found in Hanover), to a more enlightened appreciation of their humanity and their potential.

Even so, in the preface to his text, Barr (1904) still straddles this divide as he categorically writes off the severely affected, while advocating for the less impaired:

> "In endeavoring to emphasize the utter hopelessness of cure, and also the needless waste of energy in attempting to teach an idiot, I have sought to make clear the possibilities that may be attained in the training of the imbecile, the urgent need of preventing the backward child from degenerating into imbecility, and of safeguarding the absolutely irresponsible amoral imbecile from crime and its penalty."

Howe and Wilbur are credited with introducing the enlightened approach to educating individuals with ID to the United States with the establishment of training schools like those that were appearing in Europe. By the turn of the century, there were 30 such institutional settings in 21 states, both public and private, and some reserved for women, some for individuals with epilepsy. Many of these institutions had residents numbering in the hundreds, and gradually the focus shifted away from education and more toward custodial care. During their peak usage, from 1950 until the late 1960s, institutions were home to approximately 1 per 1,000 Americans. Since the mid-1960s, many fewer persons with ID have been institutionalized in the United States. This move toward "deinstitutionalization" has arisen from many sources. First, the overcrowding and neglect common in many large institutions came to light in various exposés during the late 1960s. Blatt and Kaplan's photo story, "Christmas in Purgatory" (reproduced in Look magazine), Geraldo Rivera's television reports, and Robert F. Kennedy's attacks on the Rome and Willowbrook institutions in New York all shocked the nation.

Deinstitutionalization

Other forces also led to deinstitutionalization. Perhaps the most important of these forces was the philosophy of "normalization," the idea that individuals with ID were entitled to a more normal lifestyle, including a culturally normal rhythm to one's day (school or work, leisure time, sleep), week (weekdays and weekends), and year (vacations, holidays). In 1972, Wolfensberger extended the idea of normalization to the service delivery system itself, calling on all residences, schools, and other services for persons with IDs to be as normative as possible. Parent and professional advocacy groups also fought hard for legislative and legal victories to decrease the size of large institutions.

Over the past 60 years, changes in U.S. residential institutions have been dramatic. Several states have closed their institutions, and the remaining facilities have become much smaller. Typically, individuals remaining in large or even medium-sized institutions have the most severe impairments. Many of these residents also have severe behavioral problems or motor or sensory disabilities in addition to their severe-profound ID. Overall, from 1967 to 1994, the total institutional population—defined as state-operated institutions with 16 or more residents—decreased by almost two-thirds, from 194,650 to 65,818. In California, the number of persons served by the Department of Developmental Services increased 61.6% between January 1992 and December 2001. During this same period, however, the State developmental center population decreased by 44.4%. In many states, Medicaid funding waivers (the ability to access Medicaid dollars in circumstances in which family income criteria or other eligibility criteria are waived) are in place explicitly to support children with ID who meet "institutional level of care" standards. These so-called "deeming waivers," or "Katie Beckett waivers," are meant to ensure that Medicaid support can follow an individual out of an institutional setting if such a move can be made safely and cost-effectively. Katie Beckett was a young woman in Iowa who became ventilator-dependent following a catastrophic CNS infection and whose parents discovered that if they took her home from the skilled nursing facility, she would lose her Medicaid coverage. As the costs associated with institutionalization are invariably in the tens of thousands for any individual (ranging from a low of $104,025 per year in Arkansas to a high of $375,000 in Tennessee in 2009), the cost-effectiveness criterion is rarely a limiting factor, but clinicians may be called upon to attest to the level-of-care criterion for their patients who are seeking support under this waiver.

School. Schooling is the other major service for persons with ID. Following the move to "school" all American children that began in the mid-1800s, teachers and administrators soon discovered that a subset of children was having difficulties in performing school lessons. As a result, classes for "problem children" began in many cities and towns in the late 1800s. In 1894, the first classes specifically for children with ID were formed in Providence, Rhode Island. In rapid succession, special education classes were begun in Springfield, MA (1894), Chicago (1898), Boston (1899), New York (1901), Philadelphia (1901), and Los Angeles (1902).

Local school districts have historically held an ambivalent attitude toward special education classes. Often housed within the least desirable buildings and rooms, these classes were frequently furnished with scarce equipment and materials and had few specially trained teachers. By 1968, Lloyd Dunn declared that most children with ID could be "mainstreamed" in classes with same-age students, questioning the need for segregated special education classes for most children with ID. Dunn's article took note of the Supreme Court's ruling that "separate could not be equal" in educational settings, that research had not shown that children with mild ID learn better in special education versus regular education classes and that educational techniques had advanced sufficiently to allow for the effective schooling of most children with ID alongside other children.

In both education and living settings, then, the post-1970 era witnessed the strong influence of mainstreaming, community living, and normalization. Overall, such movements have proven beneficial as persons with ID increasingly take their rightful place within modern society. Many professionals do, however, question whether normalization has sometimes gone too far. Not every child with intellectual or other disabilities may be able to be schooled optimally with typically developing peers, nor might every adult be able to live independently in the community. Indeed, some families are advocating for specialized schools or residential settings for children with autism even as state agencies fear a return to institutional approaches. These issues continue to be hotly debated among professionals, families, and organizations dedicated to improving the lives of persons with ID.

Research

Like service delivery, the modern history of research also begins in the mid-19th century. In 1838, Esquirol differentiated ID from mental illness and proposed several levels of impairment. Later in the century, various classification systems were proposed. Probably the most well-known was a system of "ethnic classifications" proposed by J. Langdon Down in 1866—hence the term "Mongolism" for persons with Down syndrome (DS), the type of ID he first identified.

In addition to classifying persons with ID, the field of genetics plays an important historic role in IDs research. Unfortunately, early in this century, that role was mainly negative. Spurred by the rediscovery of Mendel's genetic findings, some researchers attempted to show that ID was inherited. Most notorious were Dugdale's (1877) study of the Jukes, and Goddard's (1913) study of the Kallikaks. In both cases, multi-generational families were used to argue that ID was inherited, and that sterilization was necessary for the "preservation of the race." Such eugenic scares led to court decrees and sterilization laws in California and other states during the 1920s.

Also playing an important role in ID research was the new science of psychological testing. Henry Goddard, the research director at the Vineland Training School in New Jersey, was the first to use Binet and Simon's IQ tests in the United States. After testing Vineland residents over a several-year period, Goddard concluded that "the vast majority of feeble-minded children are not changing and are not improving in their intelligence levels," a finding that another leading worker, Walter Fernald, called "the most significant … and the most discouraging that we have ever known."

Since early in this century, research has progressed in both the behavioral and biomedical fields. Behaviorally, recent work has allowed for better diagnoses and classification. Nearly a century ago, psychologists invented tests of motor, nonverbal intelligence, achievement, adaptive behavior, and other skills. Following similar work with typically developing children, psychologists have learned much about the development of cognitive, linguistic, social, and adaptive skills in persons with ID. In addition, many studies now examine the presence of psychiatric disorders in children and adults with ID, and families, schools, group homes, and workshops have all received research attention. Much of this work has occurred from the 1960s until today, a time of strong, often federally supported, progress in ID behavioral research.

But arguably the most important progress has occurred in the biomedical and genetic fields. As early as 1934, the Norwegian physician, Folling, hypothesized that several of his patients with ID were unable to metabolize phenylalanine. Such insights later led to a dietary treatment of this inborn error of metabolism; the phenylalanine-free diet, though not perfect, has significantly limited PKU as a cause of ID in most industrialized countries. In addition, PKU can now be screened at birth through the Guthrie test, after which dietary treatments can be instituted. PKU remains one of the major success stories in ID research even as newer treatments for this condition are explored.

Modern genetics constitutes another success story in ID research. In 1959, Lejeune, Gautier, and Turpin discovered that most cases of DS were due to trisomy of the 21st chromosome. Fragile X syndrome (FXS), the second most common genetic cause of ID, was discovered in 1969, and its cytogenetic diagnosis was refined in the mid-1970s. With the banding techniques of the 1970s and the molecular genetic techniques of the past three decades, exact causes are being described for many of the nearly 1,500 different genetic disorders associated with ID. The genetic—and, increasingly, the behavioral—characteristics of many of these disorders are now known (see below).

Organizations

The field of ID is also a history of organizations. The first such organization was the Association of Medical Officers of American Institutions for Idiotic and Feeble-Minded Persons, which began in 1876. As the first professional group devoted exclusively to persons with ID, the Association of Medical Officers was the forerunner to the American Association on Intellectual and Developmental Disabilities (AAIDD, formerly AAMR), the field’s most influential organization. Through its various journals and committees, AAIDD has been at the forefront of research, policy, and legislative advances for persons with ID. In addition to AAIDD, other groups have played important roles, particularly concerning changes in federal policy toward people with disabilities. The Council for Exceptional Children (CEC) was begun in 1922 and continues to champion the profession of special education and the education of all children with disabilities. The Arc, formerly the National Association for Retarded Citizens (NARC), is the main parent-led advocacy group. The Arc was particularly influential in the passage of the Education for All Handicapped Children Act of 1975 (PL 94–142), the federal law that, for the first time, mandated the “free, appropriate public education” of all children with disabilities throughout the United States. Each of these groups was also influential in the passage of the Americans with Disabilities Act (ADA), federal legislation that took effect in 1992 and outlawed discrimination against persons with disabilities. The National Association for the Dually Diagnosed, now simply NADD, was established in 1983, specifically in recognition of the lack of attention by the professional community to the needs of individuals with ID who also experience psychiatric illness. Over the ensuing years, the organization has grown to be the principal association in North America to advance mental wellness for persons with developmental disabilities through the promotion of excellence in mental health care.

Federal agencies constitute an additional category of influential organizations. Begun during the presidency of John F. Kennedy (who had a sister with ID), the National Institutes of Child Health and Human Development (NICHD) have long supported disability research. Other federal programs, including the nationally distributed network of nearly 70 University Centers for Excellence in Developmental Disabilities Education, Research, and Service (UCEDDs), and NICHD-funded Mental Retardation Research Centers (MRRCs), have also played important roles in research and policy. Taken together, professional, parent, and federal organizations provide an important infrastructure to the ID field.

Before discussing definitional issues, it is worth revisiting terminology. In different countries throughout the world, different terms are used for ID. In Europe, the term “intellectual disabilities” has long been used, and a major international journal is the *Journal of Intellectual Disabilities Research*. In Great Britain, alongside “intellectual disability,” the term “learning disability” (or learning disabilities) is often used—a term with a very different meaning in the United States.

DEFINITION OF INTELLECTUAL DISABILITY

Over the years, the American Psychiatric Association (APA) has adopted definitions of ID from the AAIDD, previously the American Association on Mental Retardation (AAMR). While the definitions in the third and fourth editions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM; APA) are very similar, DSM-5 (APA, 2013) includes substantive changes to the definition of ID. For the first time in DSM, the term “intellectual disability” replaces “mental retardation,” and the language of DSM-5 is more closely aligned with that of the AAIDD. (The term proposed for ICD-11, to come into effect in 2022, is “intellectual developmental disorders.”) Further, severity levels are now classified by adaptive rather than intellectual function or IQ scores. This section reviews the changes (see Table 39–1 for summary).

Intellectual and Adaptive Functioning

Intellectual Functioning. Standardized intelligence tests that meet appropriate psychometric criteria for reliability and validity are commonly used to identify an ID. These instruments are summarized in Table 39–2, along with each test's age range and cognitive domains.

Both in terms of the testing situation itself and in the choice of an appropriate measure, administering such tests to people with ID is quite challenging. As people with ID have increased risks of comorbid psychiatric or behavioral disorders, examiners need to ensure that difficulties such as hyperactivity or poor frustration tolerance do not impede optimal test performance. Even in persons without behavioral challenges, certain personality characteristics may interfere with testing. Many people with ID, for example, look to others for solutions to difficult problems, and are quick to acquiesce, or become easily discouraged by failure. To minimize these problems, examiners can begin with easier tasks to provide success and incentives or rewards for effort.

For individuals who are nonverbal, there are several measures that can be selected that do not rely on expressive language (see Table 39–2). People with certain genetic syndromes (e.g., Williams syndrome, DS) also present unique test challenges, as many show syndrome-specific profiles of cognitive strength and weakness that are not easily described by a global IQ score (see phenotype section). Persons with ID and co-occurring sensory or motor deficits also require adaptation to routine test procedures. Finally, when testing individuals from some minority groups, examiners need to be sensitive to language and cultural issues, and use a multi-method test approach, especially when diagnosing persons with mild ID.

Adaptive Functioning. Edgar Doll (1935) was the first to develop a formal definition and measure of adaptive behavior. Two decades later, the AAMR (now AAIDD) officially included deficits in adaptive behavior in its definition of ID. Since that time, deficits in adaptive behavior have been formally included in all definitions of ID. However, until DSM-5, IQ score alone was used to classify individuals in terms of *severity* of ID. Table 39–3 illustrates the substantive nature of the changes in severity classification from DSM-IV to DSM-5.

Table 39–1.

A Comparison of DSM-IV and DSM-5 Diagnostic Criteria for Intellectual Disability

DSM-IV Diagnostic Criteria

A. Intellectual Function	B. Adaptive Function	C. Onset
Significantly subaverage intellectual functioning: an IQ of approximately 70 or below on an individually administered intelligence test	Concurrent deficits or impairment in present adaptive functioning (i.e., the person’s effectiveness in meeting the standards expected for their age or cultural group) in at least two of the following skill areas: communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety	The onset is before age 18 years.

DSM-5 Diagnostic Criteria

A. Intellectual Function	B. Adaptive Function	C. Onset
Deficits in intellectual function, such as reasoning, problem solving, planning, abstract thinking, judgment, academic	Deficits in adaptive functioning that result in failure to meet developmental and socio-cultural standards for	Onset of intellectual and adaptive deficits during the developmental period

learning, and learning from experience, confirmed by both clinical assessment and individualized, standardized intelligence testing	personal independence and social responsibility. Without ongoing support, the adaptive deficits limit functioning in one or more activities of daily life, such as communication, social participation, and independent living across multiple environments, such as home, school, work, and community.

Data from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed. American Psychiatric Association; 1994 and American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022.

Though meanings vary, adaptive behavior is typically viewed as the performance of behaviors required for social and personal sufficiency. Further, adaptive behavior is an inherently developmental and social construct. Adaptive behavior changes as children grow into adolescence and adulthood and demands for social adaptation are also defined by expectations from others—from one’s family, society, and culture. Adaptive skills typically change across various settings. One’s adaptive performance on the job or at school may differ from one’s adaptive functioning with friends or at home. Measurements of adaptive behavior, then, need to have a developmental orientation, to be socially and culturally sensitive, and to represent the many settings in which people live, work, and play.

In contrast to Doll’s time, many instruments now exist that measure adaptive behavior across multiple domains (e.g., community skills, self-care, and home living). Table 39–4 summarizes commonly used measures of adaptive behavior, their age ranges, and the domains assessed. Although most of these measures are administered as interviews with parents or other care providers, some measures are administered directly to persons with ID. Central to all measures of adaptive function is the idea that adaptive behavior is measured by performance as opposed to ability. If people with ID are able to (possess the skills to) perform certain behaviors, but do not regularly do so or do not do so without prompts, reminders, and/or assistance, then they necessarily have compromised adaptive functioning.

Table 39–2.
Measures for Assessing Intellectual Ability

Measure	Age Range (years)	Domains Assessed
Wechsler Preschool and Primary Scale of Intelligence, 4th ed. (WPPSI-IV)	2.6 to 7–3	Verbal IQ, performance IQ, full scale IQ
Wechsler Intelligence Test for Children, 5th ed. (WISC-V)	6 to 16–11	Verbal IQ, performance IQ, full scale IQ
Wechsler Adult Intelligence Scale, 4th ed. (WAIS-IV)	16–90	Verbal IQ, performance IQ, full scale IQ
Stanford–Binet Intelligence Scales, 5th ed.	2 to 85+	Verbal, quantitative, abstract/visual, short-term memory, composite score
Kaufman Assessment Battery for Children, 2nd ed., NU (KABC-II-NU)	3–18	Sequential and simultaneous processing, mental processing composite
Kaufman Adolescent and Adult Intelligence Test (KAIT)	11 to 85+	Crystallized and fluid scales, composite IQ
Differential Ability Scales, 2nd ed. (DAS-II)	2–6 to 17–11	Verbal, nonverbal reasoning, spatial abilities, general conceptual ability
Raven’s Coloured Progressive Matrices (CPM)	5 to older adults	Figural reasoning; group test
Test of Nonverbal Intelligence, 4th ed. (TONI-4)	6–0 to 89–11	Intelligence, aptitude, abstract reasoning, and problem solving

Leiter International Performance Scale, 3rd ed. (Leiter-3)	3 to 75+	Game-like tasks assessing cognitive, attentional, and neuropsychological abilities
Universal Nonverbal Intelligence Test, 2nd ed. (UNIT-2)	5–0 to 21–11	Reasoning, memory, symbolic, and nonsymbolic tasks

Severity of Intellectual Disability

There are remarkably variable strengths and competencies of people with ID. DSM-5 (similar to AAIDD 2002) provides a classification system based on adaptive functioning across three domains: conceptual, social, and practical. Table 39–3 summarizes the classification system in DSM-IV (by IQ score) and the DSM-5 system based on characteristics across the three domains and associated with mild, moderate, severe, and profound ID. As people with ID can also be classified by the etiology of their conditions, later sections detail how adaptive functioning changes across diverse genetic and other etiologic groups.

Table 39–3.

DSM-IV Severity Criteria for Intellectual Disability (APA, 1994)

Severity Criteria				
Mild	**Moderate**	**Severe**	**Profound**	**Unspecified**
IQ level 50–55 to approximately 70	IQ level 35–40 to 50–55	IQ level 20–25 to 35–40	IQ level below 20–25	When there is a strong presumption of ID but the person's intelligence is untestable by standard tests.

DSM-5 Severity Criteria for Intellectual Disability (APA, 2013)

Severity Criteria	Conceptual Domain	Social Domain	Practical Domain
Mild	For preschool children, there may be no obvious conceptual differences. For school-age children and adults, there are difficulties in learning academic skills involving reading, writing, arithmetic, time, or money, with support needed in one or more areas to meet age-related expectations. In adults, abstract thinking, executive function (i.e., planning, strategizing, priority setting, and cognitive flexibility), and short-term memory, as well as functional use of academic skills (e.g., reading, money management), are impaired. There is a somewhat concrete approach to problems and solutions compared with age-mates.	Compared with typically developing age-mates, the individual is immature in social interactions. For example, there may be difficulty in accurately perceiving peers' social cues. Communication, conversation, and language are more concrete or immature than expected for age. There may be difficulties regulating emotion and behavior in age-appropriate fashion; these difficulties are noticed by peers in social situations. There is limited understanding of risk in social situations; social judgment is immature for age, and the person is at risk of being manipulated by others (gullibility).	The individual may function age-appropriately in personal care. Individuals need some support with complex daily living tasks in comparison to peers. In adulthood, supports typically involve grocery shopping, transportation, home and childcare organizing, nutritious food preparation, and banking and money management. Recreational skills resemble those of age-mates, although judgment related to well-being and organization around recreation requires support. In adulthood, competitive employment is often seen in jobs that do not emphasize conceptual skills. Individuals generally need support to make health care–related and legal decisions, and to learn to perform a skilled vocation competently. Support is typically needed to raise a family.
Moderate	All through development, the individual's conceptual skills lag markedly behind those of peers. For preschoolers, language and pre-academic skills develop slowly. For school-age children, progress in reading, writing, mathematics, and understanding of time and money occurs slowly across the school years and is markedly limited compared with that of peers. For adults, academic skill development is typically at an elementary level, and support is required for all use of academic skills in work and personal life. Ongoing assistance on a daily basis is needed to complete conceptual tasks of day-to-day life, and others may take over these responsibilities fully for the individual.	The individual shows marked differences from peers in social and communicative behavior across development. Spoken language is typically a primary tool for social communication but is much less complex than that of peers. Capacity for relationships is evident in ties to family and friends, and the individual may have successful friendships and sometimes romantic relations in adulthood. However, individuals may not perceive or interpret social cues accurately. Social judgment and decision-making abilities are limited, and caretakers must assist with life decisions. Friendships with typically developing peers are often affected by communication or social limitations. Significant social and communicative support is needed in work settings for success.	The individual can care for personal needs involving eating, dressing, elimination, and hygiene as an adult, although an extended period of teaching and time is needed for the individual to become independent in these areas, and reminders may be needed. Similarly, participation in all household tasks can be achieved by adulthood, although extended teaching and ongoing supports are needed for adult-level performance. Independent employment in jobs that require limited conceptual and communication skills can be achieved, but considerable support from coworkers and others is needed to manage social expectations, job complexities, and responsibilities such as scheduling, transportation, health benefits, and money management. A variety of recreational skills can be developed but require supports and learning opportunities over an extended period. Maladaptive behavior is present in a significant minority and causes social problems.
Severe	Attainment of conceptual skills is limited. The individual generally has little understanding of written language or of concepts involving numbers, quantity, time, and money. Caretakers provide extensive supports for problem solving throughout life.	Spoken language is quite limited in vocabulary and grammar. Speech may be single words or phrases and may be supplemented through augmentative means. Communication is focused on the here and now. Language is used for social communication more than explication. Individuals understand simple speech/gestures. Relationships with familiar others are a source of pleasure and help.	The individual requires support for all activities of daily living (meals, dressing, bathing, and elimination), requires supervision at all times, and cannot make responsible decisions regarding well-being of self or others. In adulthood, tasks at home, recreation, and work require ongoing support/assistance. Skill acquisition in all domains involves long-term teaching and support. Maladaptive behavior, including self-injury, is present in a significant minority.
Profound	Conceptual skills generally involve the physical world rather than symbolic processes. The individual may use objects in goal-directed fashion for self-care, work, and recreation. Certain visuospatial skills, such as matching and sorting based on physical characteristics, may be acquired. However, motor and sensory impairments may prevent functional use of objects.	The individual has very limited understanding of symbolic communication in speech or gesture. They may understand some simple instructions or gestures. The individual expresses their own desires and emotions largely through nonverbal, nonsymbolic communication. The individual enjoys relationships with familiar others, and initiates and responds to social interactions through gestural and emotional cues. Sensory and physical impairments may prevent many social activities.	The individual is dependent on others for all aspects of daily physical care, health, and safety, although he/she may participate in some of these activities as well. Individuals without severe physical impairments may assist with daily work tasks at home, like carrying dishes to the table. Simple actions with objects may be the basis of participation in some vocational activities with high levels of support. Recreational activities may involve music, movies, walks, or participating in water activities, all with support. Physical and sensory impairments are frequent barriers to home, recreational, and vocational activities. Maladaptive behavior is present in a significant minority.

Table 39–4.
Common Measures of Adaptive Behavior

Measure	Age Range	Domains Tested
Vineland Adaptive Behavior Scales, 3rd ed. (Sparrow, Cicchetti, and Saulnier, 2016)	Birth–90: Interview and Parent/Caregiver Form; 3–21: Teacher Form	Communication: receptive, expressive, written; daily living skills: personal, domestic, community socialization: interpersonal relations, play and leisure, coping skills; motor skills: fine, gross
Adaptive Behavior Assessment System, 3rd ed. (ABAS-3); (Harrison and Oakland, 2015)	Birth to 89–11	Assesses conceptual, social, and practical aspects of adaptive behavior, as well as 11 skill areas within 3 major adaptive domains: Conceptual, Social, and Practical.
Scales of Independent Behavior, Revised (SIB-R) (Bruininks, Woodcock, Weatherman, and Hill, 1996)	Birth to 80+	Motor: fine, gross Social interaction and communication: social interaction, language comprehension, language expression Personal living skills: eating and meal preparation, toileting, dressing, community living skills: time and punctuality, money and value, work
Diagnostic Adaptive	4–21	Focuses on the critical

Behavior Scale (DABS) (AAIDD release 2015)		“cut-off area” for the purpose of ruling in or out a diagnosis of ID or related disability.
Street Survival Skills Questionnaire (SSSQ) (Linkenhoker and McCarron, 1993)	9–40+	Administered to person; basic concepts, functional signs, tools, health

Mild Intellectual Disability. Mild ID constitutes the largest group of people with ID, possibly as many as 85% of all persons with ID. These individuals appear similar to unaffected individuals and often blend into the general population in the years before and after formal schooling. Many achieve academic skills at the sixth-grade level or higher, and some graduate from high school. As adults, many of these individuals hold jobs, marry, and raise families—yet at times they may appear slow or need extra help negotiating life’s problems and tasks. Historically, people with mild ID were thought to show relatively few clear-cut organic causes for their delay. However, in recent years there has been an increase in the number of people with genetic syndromes who function in the mild range of ID. Examples include most people with Prader–Willi syndrome (PWS), as well as some males and most females with FXS .

A more striking finding is that more people with mild ID come from minority groups and low socio-economic (SES) backgrounds than would be expected from their percentages in the general population. This overrepresentation of minority groups has been used to criticize standardized intelligence tests that are used for placement in special education classroom settings, as well as to highlight the importance of environmental-cultural influences on intellectual development and assessment.

Moderate Intellectual Disability. Moderate ID is seen in approximately 10% of the population with ID and includes people with more impaired cognitive and adaptive functioning. People with moderate ID are typically diagnosed in their preschool years, and some show a clear organic cause for their delay. Many persons with DS, the most common chromosomal cause of ID, often function in this range, as do many adolescents and adults with FXS . Most children with moderate ID require special education services, achieving academic skills at the second to third grade level. Need for supportive services continues throughout the lifespan, and with proper supports, many live, work, and thrive in their local communities. In a study by Ross and colleagues, 20% of persons with IQs from 40 to 49 lived independently, whereas 60% were considered partially dependent and 20% totally dependent on others. In a similar way, some individuals in this range are employed in the competitive job market, and need minimal job supervision, whereas others require more extensive supervision on the job, and may work in sheltered workshops or other, more segregated settings.

Severe Intellectual Disability. Severe ID occurs in about 3% to 4% of the population of people with ID. Individuals at this level often have one or more organic causes for their delay, and many show concurrent motor, ambulatory, and neurologic problems, as well as poorly developed communication skills. Most persons with severe ID require close supervision and specialized care throughout their lives. Some individuals learn to perform simple tasks or routines that facilitate their self-care or their ability to perform in a sheltered workshop or pre-workshop type of setting.

Profound Intellectual Disability. Profound ID affects relatively few individuals (1% to 2%) with ID, and involves pervasive deficits in cognitive, motor, and communicative functioning. Impairments in sensory-motor functioning are often seen from early childhood on, and most individuals require extensive training to complete even the most rudimentary aspects of self-care such as eating and toileting. Most people with profound ID have identifiable organic causes for their delay, and most require total supervision and care throughout life. These four levels—mild, moderate, severe, and profound—have long been used to classify severity of ID yet have come under attack because of their focus on deficits instead of competencies. How people with ID are defined and classified—based on strengths, impairments, or some combination of both—has profound implications for studies on the epidemiology of this condition.

PREVALENCE

According to DSM-5, 1% of the population has an ID. Indeed, a meta-analysis of 52 peer-reviewed papers has estimated the global prevalence of ID to be 1,037 per 100,000 population. When stratified by severity, 3 to 4 in 1,000 have severe ID while 5.4 to 10.6 in 1,000 have mild ID (Martin et al., 2018). Rates are higher in males (perhaps due to greater risks of environmental exposures or X-linked conditions), generally low in the early years, peak around ages 10 to 14, and decrease in the late school years and adulthood. However, a recent epidemiologic study based on a national register in Sweden found that the prevalence of ID in older adults is increasing as a result of medical and social advances, and that approximately 0.5% of the population above 55 years of age has ID. Individuals of lower socioeconomic status and of ethnic minority groups show higher-than-expected rates of ID, likely secondary to lack of access to obstetric care, higher rates of environmental toxins, low access to healthy diet options and lower access to education (Thapar et al., 2015). When prevalence rates are adjusted for age, birth order, and economic status the risk associated with minority group status is reduced to eliminated. Genetic variability among ethnic groups is not suspected to be a major factor.

Etiology of Intellectual Disability

As noted by Esquirol in 1845, ID is not a disease in and of itself, but the developmental consequence of a variety of pathogenic processes. ID results from brain dysfunction, generally due to abnormal brain development or brain injury resulting from genetic and environmental causes (Table 39–5). Many genetic causes of ID have been known for decades, while modern genetic techniques have identified hundreds of new causes of ID.

Genetic causes of ID can result in multiple malformation conditions (e.g., DS) or what appears to be “non-syndromic” ID. That said, most genetic causes of ID are associated with characteristic clinical or neurobehavioral features, if the patients are examined thoroughly. Genetic disorders with ID display a wide variety of inheritance patterns and genetic mechanisms including chromosome rearrangements (often de novo), autosomal recessive, autosomal dominant (inherited and de novo), X-linked, triplet repeat expansion, and imprinting. The important role for de novo mutations has only recently been appreciated. Knowledge of these genetic mechanisms can aid with diagnosis and is essential for recurrence risk counseling. More and more, the genetic diagnosis influences treatments to implement (e.g., specific melatonin/propranolol treatment for sleep disruption in patients with Smith–Magenis syndrome) and treatments to avoid (e.g., valproate in ornithine transcarbamylase deficiency). In addition, some disorders are associated with health implications for family members (e.g., fragile X–associated tremor/ataxia syndrome [FXTAS] and premature ovarian failure in adult relatives of individuals with fragile X).

Table 39–5.
Etiologic Classification of Intellectual Disability

Etiology	Examples	Estimated Frequency (%)
A. Prenatal Causes		
1. Genetic disorders		4–28
Chromosomal aberrations	Down syndrome	
Monogenic mutations	Tuberous sclerosis; phenylketonuria and other metabolic disorders; fragile X syndrome	
Multifactorial	“Familial” mental retardation	
Malformation syndromes due to microdeletions	Prader–Willi, Williams, Angelman syndromes	
2. Congenital malformations		7–17
Malformations of the central nervous system	Neural tube defects	
Multiple malformation syndromes	Cornelia de Lange syndrome	
3. Exposure		5–13
Maternal infections	Congenital rubella, HIV	
Teratogens	Fetal alcohol syndrome	
Toxemia/placental insufficiency	Prematurity	
Other	Radiation, trauma	

B. Perinatal Causes		2–10
1. Infections	Meningitis	
2. Delivery problems	Asphyxia	
3. Other	Hyperbilirubinemia	
C. Postnatal Causes		3–12
1. Infections	Encephalitis	
2. Toxins	Lead poisoning	
3. Other postnatal causes	Traumas, brain tumors	
4. Psychosocial problems	Poverty, psychotic illness	
D. Unknown Causes		30–50

With advances in medicine generally and in molecular genetics in particular, new causes of ID, or the genetic etiologies of formerly unspecified syndromes, are identified each year. For example, a national database of genetic disorders, *Online Mendelian Inheritance in Man,* lists >2,500 genetic conditions associated with ID. The most common causes of ID include DS, FXS, prematurity, and fetal alcohol syndrome. Variability in patient cohorts and methods for defining etiologies make it difficult to estimate the proportion of patients accounted for by each cause. For example, persons drawn from institutional settings, where severe and profound ID and visible congenital anomalies are more likely to be found, more commonly have an identifiable chromosomal abnormality than do persons with mild disability residing in community settings.

Understanding the cause of ID in an individual person is essential for providing prognostic information, guiding treatment, and educating families about recurrence risk. For instance, distinguishing between a one-time injury such as hypoxia and a genetic neurodegenerative disorder such as a lysosomal storage disorder makes a huge difference in treatment, emotional impact on the family, how they plan their child’s life, and how they approach having additional children. A specific diagnosis can also reduce family stress by providing an "answer" for why their child has a significant disability and allowing them to connect with other families affected by the same condition. More and more, an accurate diagnosis will guide more appropriate treatments to maximize neurocognitive function, prevent decline, and direct specific medical screenings or treatments that optimize the patient's health and adaptive function.

In the era of rapidly expanding molecular genetic diagnosis, each provider must decide how to manage the explosion in genetic information and the impact on diagnosis and treatment based on their level of interest, educational background, and access to other subspecialists. At a minimum, psychiatric providers need to know when to suspect an underlying genetic condition and how to ensure adequate evaluation and management (through reference materials and/or consultants). For instance, ornithine transcarbamylase deficiency results from a defect in the urea cycle that can cause encephalopathy due to elevated ammonia levels. Patients can present at any age, and the best way to improve behavioral issues in a patient with undiagnosed or inadequately treated ornithine transcarbamylase deficiency, is to recognize the possibility of the condition, diagnose it using biochemical (plasma ammonia level) and genetic testing (*OTC* gene sequencing), and provide dietary and medication treatment to lower ammonia levels and maintain nutrition. Valproate, haloperidol, and other medications should also be avoided, since they have been associated with hyperammonemic crises in these patients. Indeed, the decompensation associated with administration of these medications in an undiagnosed patient can prompt workup and accurate diagnosis of ornithine transcarbamylase deficiency by the vigilant psychiatrist. Genetic diagnosis is now directly influencing treatment choices in a variety of diseases, most prominently cancer, and it is only a matter of time before gene-specific treatments become widespread in psychiatry.

Medical Diagnostic Approach to the Patient With Intellectual Disability

Clinical History and Examination. The elements of a comprehensive clinical evaluation for the patient with ID are summarized in Table 39–6. As for any patient, a good history is essential, and in many cases collateral information is extremely useful. Family members may be able to fill in important aspects of the family pedigree, providing information about relatives ranging from learning problems to physical anomalies, developmental disabilities, and even response to treatment.

The clinical examination should be performed with particular attention to the presence of minor anomalies, aberrant growth, and physical development (see Table 39–6). Increasingly, the examination will look for behavioral symptoms that may comport with a known behavioral phenotype (see later discussion) and help in diagnosis.

Genetic Evaluation. Given the incredible advances in DNA sequencing technologies and other methods for identifying mutations across the entire human genome, clinical genetic testing in patients with ID is very much a moving target. Currently, patients without an obvious syndrome or extrinsic cause should be evaluated for chromosomal abnormalities and fragile X (by chromosomal microarray and fragile X repeat length testing, respectively), since these are the most common causes of “nonsyndromic” ID. Genetic disorders should still be considered in patients who do not follow the expected course for a presumed environmental cause. Unless a specific aneuploidy (such as trisomy 21) or a balanced translocation is suspected, a karyotype is no longer the appropriate test when chromosome microarray is available. Beyond these basic tests, expert clinical genetics consultation may be the most cost-effective next step, rather than extensive laboratory testing and imaging. Genetic consultation can help guide diagnostic testing as well as providing counseling about prognosis, surveillance for complications, and recurrence risk.

When a specific disorder is suspected, a single-gene test may be the best option; however, as genetic testing becomes more widely available, the spectrum of presentations associated with each gene has broadened, so it can be difficult to determine which single-gene test to perform. Fortuitously, DNA sequencing has become much more efficient, so panels of genes, or even most of the coding regions in the entire genome (the “exome”), can now be sequenced in a single test. As the cost of sequencing decreased and human sequence variation becomes better characterized, genome-wide sequencing methods will become first-line genetic tests, despite the challenges with interpreting the significance of many DNA variants. It is important to remember that currently available sequencing tests do not detect repeat expansions or imprinting disorders.

Table 39–6.

Elements of the Clinical Evaluation of the Patient with Intellectual Disability

Clinical History

Prenatal exposures (alcohol, infections, etc.)

Birth history

CNS infection, traumatic brain injury

Developmental regression

Focal neurologic findings, hypertonia, hypotonia, or ataxia

Extra-CNS malformations and medical issues

Visual impairment or hearing loss

Family Pedigree (Three-Generation)

Relatives with learning problems, psychiatric disorders, intellectual disability, abnormal brain imaging findings, neurologic or degenerative disorders

Consanguinity

Family resemblance (reduced between family members with and without some genetic conditions)

Physical Examination

Assessment of major and minor physical anomalies including facial features and skin findings

Growth and physical development

Head circumference compared to norms (congenital versus “acquired” microcephaly/macrocephaly)

Growth trajectory (comparison with earlier measures)

Description of facial features (micrognathia, hypertelorism, thin upper lip)

Complete neurologic examination

Skin examination for café-au-lait and other birthmarks

Documentation of behavioral phenotype

Adjunct Diagnostics

Hearing evaluation

Ophthalmology evaluation of eye structure, eye movements, and visual function

Psychometric assessments

Laboratory Testing (When Indicated)

Creatine kinase (to evaluate for muscular dystrophies)

7-dehydrocholesterol testing if Smith–Lemli–Opitz syndrome is suspected

Metabolic studies for lysosomal, peroxisomal, and mitochondrial disorders

Urine organic acids, plasma amino acids

Congenital disorders of glycosylation testing

Genetic Testing (When Indicated)

Chromosomal microarray

Fragile X testing

DNA sequencing (single gene, gene panel, whole exome)

DNA methylation testing if Prader–Willi or Angelman syndromes are suspected

Imaging

Structural brain magnetic resonance imaging (MRI)

Functional brain MRI (fMRI; still largely research-based)

Diffusion tensor brain MRI (DTI)

Other Studies

Muscle biopsy for suspected mitochondrial disease (or muscular dystrophy)

Neuroimaging. Neuroimaging is clinically indicated for individuals with ID in the presence of microcephaly or macrocephaly, abnormal head circumference, seizures, focal neurologic signs, and/or progressive cognitive impairment or loss of psychomotor skills. MRI is generally superior to CT unless acute hemorrhage or calcification are suspected. MRI has been useful in elucidating a diagnosis in around 5% of people with nonprogressive ID (Decobert et al., 2005). More commonly, in ~50% of patients, subtle and nonspecific structural findings indicating altered neurodevelopment are present such as ventriculomegaly, dysplasia of the corpus callosum, minor abnormalities of white matter signal, cortical gyration, and cerebellar vermis. The American Academies of Neurology and Pediatrics and the American College of Medical Genetics periodically publish updated practice guidelines for the use of brain imaging in the evaluation of patients with ID. Magnetic resonance spectroscopy is lower-yield and less commonly employed, although it can yield a diagnosis when a metabolic disorder is suspected despite otherwise normal genetic and metabolic work-up. Diffusion tensor imaging holds promise for identifying disorders associated with defects in major axon pathways that do not affect brain morphology; however, it is not yet in wide clinical use. The use of MRI technology to study brain structure and regional activation (fMRI) and white matter tracts (diffusion tensor imaging) remains a powerful potential tool in the study of ID and their underlying mechanisms. Information gathered from MRI research studies have shown neuroanatomical and functional effects of specific genetic disorders associated with mental retardation (Gothelf et al., 2005). However, large studies utilizing structural MRI or quantitative methods such as those performed in ADHD or autism have not been performed in ID, and research involving the use of functional MRI (fMRI) in ID is still emerging. Advanced imaging techniques may serve to better elucidate the neurobiology of ID, resulting in improved diagnostic precision and treatment monitoring in the future.

Electroencephalography. Electroencephalographic investigations, such as waking/sleep video-EEG-polygraphic studies may be useful in patients with a clinical history of seizures and those with severe language deficits and/or specific genetic syndromes such as Angelman syndrome. EEGs are often requested in patients with known cortical malformations associated with high seizure risk (e.g., polymicrogyria) when acute behavioral or cognitive changes have occurred.

Metabolic Testing

EVALUATION FOR INBORN ERRORS OF METABOLISM. The Inborn Errors of Metabolism (IEMs) or biochemical genetic conditions are a large and fast-growing group of disorders that are for the most part individually quite rare, but collectively affect 1% to 1.5% of the population. These disorders originate from disruptions to genes involved in biochemical and metabolic pathways, many of which are important in brain development and/or function. In general, symptoms and findings arise from either the accumulation of substances that prove toxic in excess or the inability to synthesize enough of a required product. Well-known IEMs causing ID include phenylketonuria (PKU), Lesch–Nyhan syndrome, and the lysosomal and glycogen storage diseases. It is important for the practicing clinician to retain the IEMs in the differential diagnosis, since many require specialized treatment to prevent morbidity, progression, and mortality, as well as to optimize development. Frequently, treatment involves supplementation with a deficient enzyme or metabolic intermediate with or without dietary restriction. It should be noted that each IEM may have variant ages of onset such as "infantile," "juvenile," or "adult" forms, with concomitantly different mixes of medical and neuropsychiatric symptoms. Later-onset forms may manifest in less medically severe findings and a presentation more dominated by neuropsychiatric symptoms. Specific features in each disorder vary, but the child psychiatrist should consider the IEMs in the differential diagnosis of every individual with ID.

Table 39–7.
Selected Clinical Findings and Laboratory Abnormalities Which Increase Suspicion for Underlying Metabolic Disorder

Growth abnormality
Recurrent, unexplained illness
Exacerbation of symptoms by physiologic stress
Seizures
Ataxia
Loss of psychomotor skills
Hypotonia
“Coarse” appearance
Eye abnormalities (cataracts, ophthalmoplegia, corneal clouding, retinal abnormality)
Recurrent somnolence/coma
Abnormal sexual differentiation
Arachnodactyly
Hepatosplenomegaly
Metabolic/lactic acidosis
Hyperuricemia
Hyperammonemia
Low cholesterol
Structural hair abnormalities
Unexplained deafness
Bone abnormalities (dysostosis; occipital horns; punctate calcifications)
Skin abnormalities (angiokeratoma; “orange-peel” skin, ichthyosis)
Brain imaging abnormalities cortical and/or cerebellar atrophy, evidence of stroke, abnormal white matter signal, lactate peak on MRS

Adapted from Curry CJ, Stevenson RE, Aughton D, et al. Evaluation of mental retardation: recommendations of a consensus conference. *Am J Med Genet.* 1997;72(4):468–477.

While guidelines published by the American Academies of Pediatrics and Neurology do not recommend routine metabolic testing for all persons with ID, several studies suggest that IEMs may account for up to approximately 2.5% of patients after screening by clinicians. More recent studies have shown that even after broad-based metabolic screening, a second line of testing identified IEMs in 14% of patients, many of which were treatable (Engbers et al., 2008). A careful history should be taken to make sure the patient received usual newborn screening tests (particularly in the case of immigrants or where the patient lacked usual perinatal care) and whether the testing followed current recommendations (especially in older individuals). IEMs should be particularly considered in the patient with ID who presents with catatonia, mania, seizures, encephalopathy, and/or visual hallucinations, when symptoms appear exacerbated by physiologic stress and illness, occur with abdominal pain or vomiting, or functional regression (Table 39–7).

The authors recommend the following screening labs for patients with ID when an IEM is suspected: complete blood count, complete metabolic panel (electrolytes, BUN, creatinine, glucose, transaminases), lactate, pyruvate, urine organic acids, plasma amino acids, ammonia, plasma acylcarnitines, and total and free carnitine. Testing during a symptom exacerbation is recommended, since assays may be normal during periods of relative metabolic stability. Referral to a specialist biochemical geneticist is also recommended for evaluation and/or management.

GENETIC INTELLECTUAL DISABILITY SYNDROMES AND BEHAVIORAL PHENOTYPES

Remarkable genetic advances have sparked renewed research interest in the behavioral features of persons with fragile X, Prader–Willi, and other genetic syndromes. In their reviews in the 1970s of behavioral aspects of chromosomal disorders, S. Kessler and R. Moos, for example, discussed only five syndromes. Since that time, the number of disorders for which a “behavioral phenotype” has been suggested has grown considerably. A good working definition of a “behavioral phenotype” is that proposed by Dykens, namely, that of a syndrome in which the probability of the expression of certain behaviors or constellations of behaviors is greater than what would otherwise be expected. Stereotyped hand movements, for example, have been described in many contexts, but a particular form of stereotyped hand wringing is almost invariably seen in Rett syndrome. Hyperphagia and obesity are nonspecific symptoms, but without aggressive dietary intervention, the probability of an individual with PWS becoming obese is nearly 100%.

Table 39–8 provides a representative sample of syndromes for which behavioral phenotypes have been described—some anecdotally, others with controlled studies. Although the study of behavioral phenotypes is only at its beginning stages, this line of work holds much promise for both clinicians and researchers. Identifying syndrome-specific behavioral patterns helps clinicians to zero in on some diagnostic possibilities over others, and these behavioral profiles also guide intervention and treatment. From a research standpoint, phenotypic work advances the understanding of gene–brain–behavior relationships. To illustrate these advantages, the following subsections review behavioral and genetic features for fragile X, Prader–Willi, Down, and Williams syndromes. Although not representative of all syndromes, these examples amply demonstrate the promise of phenotypic research for both intervention and science.

Examples of Behavioral Phenotypes in Intellectual Disability Syndromes

Fragile X Syndrome. FXS, the most common inherited cause of ID, results in a wide range of learning and behavioral problems, with males being more often and more severely affected than females. The fragile X gene (*FMR1*) represents a relatively newly identified type of human disease, caused by an amplification (or excessive repetition) of trinucleotide sequences (CGG) that make up DNA. Greater than 200 triplet repeats, people are fully affected with the syndrome. Numbers of repeats between 55 and 200 are termed “premutations.” One in 148 to 291 females, and one in 290 to 855 males may carry the premutation, with approximately 1 in 4,000 males and 1 in 8,000 females being fully affected with the syndrome.

Many of the behavioral features in people with FXS are a function of the number of CGG repeats and a cascade of subsequent effects. The number of repeats relates to the degree that the *FMR1* gene is methylated and subsequently silenced or blocked from transcription and translation. This, in turn, affects the amount of *FMR1* protein (FMRP) produced, and the range of clinical expression in FXS is associated with the amount of FMRP. Fully affected, fully methylated males have no FMRP, whereas high-functioning males, although rare, have some FMRP via CGG size and/or methylation mosaicism. In affected females, only one X chromosome carries the *FMR1* gene, whereas the other produces some FMRP. Because all females have one X chromosome that is randomly inactivated in all cells, the degree of involvement in females with fragile X is at least in part related to the ratio of cells that have affected X active to silenced (inactive). About half of fully affected females thus show mild to moderate ID, whereas half have average IQ but show learning difficulties and/or social affective impairments. Both males and females with the full syndrome exhibit similar neurocognitive profiles, including deficits in auditory short-term memory, processing of sequential information, and attention, with relative strengths in processing simultaneous information, long-term memory, and distinguishing between one’s own and others’ representations of the world.

Although FXS is a genetic disorder, there is also evidence for environmental contributors to IQ and other specific neurocognitive deficits, including factors relating to the home environment (enrichment opportunities and socioeconomic status). All of these factors taken together—gender, variation in the *FMR1* repeats, and environment—contribute to the significant within-syndrome variability found in FXS.

Fragile X Syndrome, Autism Spectrum Disorder (ASD), and Other Comorbidities. It has been reported that many fully affected males with FXS show symptoms consistent with ASD such as language delay, echolalia, stereotypies, self-injurious behavior (SIB), perseveration, poor eye contact, and tactile defensiveness. Therefore, it is not surprising that early workers wondered whether FXS would reveal a common genetic cause of ASD. Studies to examine the prevalence rate of ASD among individuals with FXS has been somewhat inconsistent, partly due to variable methodology and revised diagnostic criteria for ASD, with prevalence rates ranging from 5% of males with FXS having autistic disorder to half of males and nearly 20% of females with FXS meeting DSM-5 criteria for ASD.

In addition, social and performance anxiety, slow-to-warm up temperament, including shyness, social withdrawal, mutual gaze aversion, hyperarousal, hyperactivity, and attention deficits are common among individuals with FXS. Attention-deficit/hyperactivity disorder (ADHD) symptoms are higher among affected boys relative to control subjects, and girls with FXS have lower prevalence rates of ADHD than boys with FXS. Among adults, problems in attending and in sustaining effort have been found in the neuropsychological profiles of women with expanded *FMR1* repeats, which may contribute to problems in math, abstract reasoning, and planning.

FXS thus involves vulnerabilities toward shyness, gaze aversion, social anxiety, avoidant disorders, schizotypal disorder, ADHD, and ASD. These difficulties vary in severity but are typically found in persons across the IQ spectrum, from those with moderate ID to those with mild learning disabilities.

Individuals with premutation (typically family members of affected individuals) are also at risk for psychiatric and medical issues including social dysfunction, primarily shyness, gaze aversion, and social anxiety and the adult-onset FXTAS. FXTAS is characterized by progressive intention tremor and gait ataxia, with associated dementia and global brain atrophy resulting in significant morbidity and mortality.

Prader–Willi Syndrome. First identified in 1956, PWS affects about 1 in 15,000 births and is best known for its food-related characteristics. Whereas babies with PWS invariably show hypotonia and pronounced feeding-sucking difficulties, young children between

2 and 6 years of age develop hyperphagia and food-seeking behavior such as food foraging and hoarding. Hyperphagia is likely associated with a hypothalamic abnormality resulting in a lack of satiety. Food preoccupations are lifelong, and without prolonged dietary management, affected individuals invariably become obese. Indeed, complications of obesity remain the leading cause of death in this syndrome.

PWS is the first known human disease to show the effects of genomic imprinting, in which genes are modified and expressed differently depending on whether they are inherited from the mother or the father. PWS is caused by the loss of the paternal copy of the PWS “critical region” on chromosome 15q11.2–13, whereas loss of the maternal copy of 15q11.2–13 results in a completely different and more severe developmental disorder, Angelman syndrome. Up to 70% of PWS cases are caused by a paternally derived deletion on the long arm of chromosome 15. Less than 5% of PWS cases are caused by a defect in the imprinting center. The remaining cases are attributed to maternal uniparental disomy (UPD) of chromosome 15, in which both members of the chromosome 15 pair come from the mother. The prevalence of PWS by UPD is reportedly increasing, likely due to the recent trend of advancing maternal age.

Table 39–8.

Phenotypes of Selected Conditions Associated with Intellectual Disability

Disorder	Cause	Inheritance	Prevalence[a]	Recurrence Risk	Testing	Clinical Features	Behavioral Phenotype
Chromosomal							
Cri-du-chat syndrome	5p15.2 deletion	Dominant deletion (usually de novo)	1/20,000–50,000	Very low	Chromosome microarray	Microcephaly, round face with hypertelorism, epicanthal folds, down-slanting palpebral fissures, broad, flat nose, low-set ears, micrognathia, prenatal growth retardation, respiratory and ear infections, congenital heart disease, gastrointestinal abnormalities	Severe ID, infantile "catlike" cry, hyperactivity, stereotypies, self-injury
Down syndrome	Trisomy 21	Sporadic	1/2,500–1/32 births based on maternal age	Low, unless due to translocation	Karyotype	Hypotonia, facial gestalt (upward-slanting palpebral fissures, flat, wide nasal bridge), single palmar crease, short stature, hypothyroidism, congenital heart disease, intestinal atresia	Moderate ID, strength in social development, hyperactivity in childhood, stubborn, verbal > auditory processing, increased risk of depression and Alzheimer-type dementia in middle age
Smith–Magenis syndrome	17p11.2 deletion	Dominant deletion (usually de novo)	1/25,000	Very low	Chromosome microarray	Broad face, flat midface, progressively coarsening facial features, short, broad hands, small toes, and hoarse, deep voice	Severe ID, hyperactivity, severe self-injury including hand biting, head banging, and pulling out finger and toe nails, stereotyped "self-hugging" and "lick and flip" behaviors, attention seeking, aggression, characteristic sleep/circadian rhythm disturbance
22q11 Deletion syndrome (Velocardiofacial/DiGeorge)	22q11 deletion	Dominant deletion (de novo or inherited)	1/4,000	Low if de novo, up to 50% if parent affected	Chromosome microarray or FISH	Congenital heart disease, cleft soft palate, long tapered digits, T-cell deficit, hypocalcemia	Variable ID, learning disability, ADHD, autism, psychosis (schizophrenia 25%)
Williams syndrome	7q11–23 deletion	Dominant deletion (usually de novo)	1/7,500	Low if de novo, up to 50% if parent affected	Chromosome microarray	Broad forehead, depressed nasal bridge, stellate iris pattern, widely spaced teeth, full lips, narrow chin, elastin arteriopathy +/– hypertension, short stature, hypercalcemia, hypothyroidism	Mild to moderate ID, anxiety (specific phobias and general anxiety), emotional lability, hyperactivity, outgoing, sociable, verbal skills > visuospatial skills
Single Gene							
Fragile X syndrome	*FMR1* trinucleotide repeat expansion	X-linked with anticipation	1/4,000 males, 1/8,000 females	Up to 50%	FXS testing for repeat length	Long face, large ears, flat midface, high, arched palate, short stature, macro-orchidism, mitral valve prolapse, joint laxity, strabismus	Variable ID (milder in females), verbal IQ > performance IQ, hyperactivity, inattention, anxiety, stereotypies, gaze aversion, social avoidance, shyness, irritability
Rett syndrome	Altered gene expression due to loss of *MECP2* function	X-linked, 99% de novo	1/8,500 females (rare in males)	Low	*MECP2* gene sequencing	Acquired microcephaly; gait ataxia and apraxia; tremors; seizures	Moderate to severe ID, regression at 6–18 months, stereotyped "wringing" hand movements, fits of screaming and inconsolable crying, autistic features, panic-like attacks, bruxism, episodic apnea and/or hyperpnea
Cornelia de Lange syndrome (Cohesinopathy)	*NIPBL, SMC1A, SMC3, RAD21, HDAC8*		1/40,000–100,000		Panel sequencing vs. exome	Continuous eyebrows, small, upturned nose, anteverted nostrils, thin, down-turned upper lip, microcephaly, short stature, small hands and feet, malformed upper limbs, failure to thrive	Severe ID, self-injury, language delays, avoidance of being held, stereotypic movements
Tuberous sclerosis complex 1 and 2	Loss of *TSC1* or *TSC2* function	Autosomal dominant	1/10,000		*TSC1/TSC2* sequencing	Hamartomas of central nervous system, skin, kidney, heart, epilepsy	Normal IQ to profound ID, social deficits, autism, hyperactivity, impulsivity, aggression, self-injury, sleep disturbance, anxiety, depression
Neurofibromatosis type[a] (RASopathy)	Loss of *NF1* function	Autosomal dominant (de novo or inherited)	1/2,500–4,000	Low if de novo, 50% if parent affected	*NF1* sequencing	Café-au-lait macules, intertriginous freckling, Lisch nodules, cutaneous neurofibromas, optic pathway glioma, short stature, and macrocephaly in 30–45%	10% moderate to profound ID (verbal IQ > performance IQ), 50% speech and language difficulties, hyperactivity, impulsivity, distractibility, anxiety
Imprinting							
Prader–Willi syndrome (PWS)	Lack of paternal-specific imprinting of 15q11.2-q13	Imprinting (90% sporadic)	1/10,000–30,000	Low, except with paternal mutation	PWS/AS methylation testing	Hypotonia, failure to thrive in infancy, obesity, small hands and feet, micro-orchidism, crypto-orchidism, short stature, almond-shaped eyes, fair hair and light skin, flat face, scoliosis, orthopedic problems, prominent forehead, and bitemporal narrowing	Mild to moderate ID, compulsive behavior, hyperphagia, hoarding, impulsivity, borderline to moderate mental retardation, emotional lability, tantrums, excess daytime sleepiness, skin picking, anxiety, aggression
Angelman syndrome (AS)	Loss of *UBE3A* function via mutation or lack of maternal-specific imprinting of 15q11.2-q13	Imprinting (90% sporadic)	1/12,000–24,000	Low, except with maternal mutation	PWS/AS methylation testing and *UBE3A* sequencing	Fair hair and blue eyes (66%); dysmorphic faces including wide, smiling mouth, thin upper lip, and pointed chin; epilepsy (90%) with characteristic electroencephalogram; ataxia; small head circumference; 2–5% microcephalic	Moderate to severe ID, happy disposition, paroxysmal laughter, hand flapping, clapping, profound intellectual disability, sleep disturbance with nighttime waking, possible increased incidence of autistic features, love of water and music (anecdotal)
Metabolic							
Smith–Lemli–Opitz	Loss of *DHCR7* function, defect in cholesterol metabolism	Autosomal recessive	1/20,000–40,000	25%	7-dehydrocholesterol level, *DHCR7* sequencing	Characteristic facial features (narrow forehead, epicanthal folds, ptosis, short mandible, short nose, anteverted nares, low-set ears), cleft palate, cardiac defects, underdeveloped male genitalia, postaxial polydactyly, and 2–3 toes syndactyly	Mild to profound ID, self-injury, hyper-reactivity, rapid body-arching movements, sleep disturbance, autism
Phenylketonuria (prototypical biochemical genetic disorder)	Accumulation of phenylalanine	Autosomal recessive	1/10,000	25%	Newborn screening, plasma amino acids	Symptoms absent neonatally, later development of seizures (25% generalized), fair skin, blue eyes, blond hair, rash	Mild to profound ID, language delay, destructiveness, self-injury, hyperactivity

Mitochondrial	Defects in electron transport chain	Autosomal recessive, autosomal dominant, X-linked or maternal	1/5,000	Up to 25%	Lactate, pyruvate, plasma amino acids, MRS, muscle biopsy	Multisystem involvement (brain, eye, heart, kidney, muscle), decompensation with physiologic stress, regression, seizures, hearing loss; can present in adulthood as psychiatric disease.	Unknown
Lesch–Nyhan syndrome	Loss of *HPRT1* function, accumulation of uric acid	X-linked	1/380,000	50% of sons	Urine urate-Cr ratio, 24-hour urine urate, *HPRT1* sequencing	Hypotonia followed by extrapyramidal movements, spasticity, severe motor disability, uric acid accumulation in kidney (calculi), joints (gout), skin (tophi)	Mild to moderate ID (after normal pre- and perinatal course), severe self-injury/biting behaviors, aggression
Ornithine Trans-carbamylase Deficiency	Loss of *OTC* function and ammonia accumulation	X-linked	1/14,000–77,000	Carrier mothers: 50% of sons; affected fathers: 50% of daughters are carriers	Ammonia level, *OTC* sequencing	Encephalopathy in response to protein ingestion or stress, respiratory alkalosis, altered mental status/delirium	Normal IQ to severe ID (more severe in males), variable age of presentation, ADHD, executive function deficits
Lysosomal storage diseases (diverse group of >50 disorders)	Accumulation of various macro-molecules	Autosomal recessive, X-linked	1/5,000–10,000	25%	Enzymatic and gene sequencing	Coarse facies, corneal clouding or macular cherry-red spot, macroglossia, dysostosis multiplex (skeletal findings), organomegaly (heart, liver, spleen), cardiac arrhythmias	Broad range of ID, gradually progressive
Toxin							
Fetal alcohol syndrome	Alcohol neurotoxicity	NA	1/3,000 in western countries, 1/300 with fetal alcohol effects	NA	Clinical diagnosis	Microcephaly, short stature, midface hypoplasia, short palpebral fissure, thin upper lip, retrognathia in infancy, micrognathia in adolescence, hypoplastic long or smooth philtrum	Mild to moderate ID, irritability, ADHD, memory impairment

*Estimated prevalence in mixed European populations.
ADHD, attention-deficit/hyperactivity disorder; ID, Intellectual Disability; IQ Intelligence Quotient.
As genetic testing has become more widespread, the known clinical presentation for each genetic disorder has expanded beyond the classic presentations described in the early literature. More and more, disorders are being grouped by their shared molecular pathophysiology, e.g., Cornelia de Lange syndrome as a cohesinopathy (defects in the cohesion DNA-binding complex involved in DNA repair, chromosome segregation, and gene regulation) and Neurofibromatosis 1 as a RASopathy (defects in the RAS/MAPK network of genes involved in cell cycle regulation and differentiation).

Although people with PWS invariably obsess about food, a remarkably high proportion of persons also show nonfood obsessions and compulsive behaviors. These nonfood symptoms include skin picking, hoarding, needing to tell, ask, or say things, and having concerns with symmetry, exactness, ordering, arranging, cleanliness, and sameness in daily routine. Often these symptoms are associated with distress or adaptive impairment, suggesting marked risks of obsessive-compulsive disorder in this population. Indeed, obsessive-compulsive disorder is many more times likely in people with PWS than in the general population of people with ID.

In addition, even as compared to others with ID, children and adults with PWS show high rates of temper tantrums, aggression, stubbornness, underactivity, excessive daytime sleepiness (in part, related to central and/or obstructive sleep apnea syndromes) and emotional lability. Coupled with food seeking, these impulsive behaviors often lead people with PWS to need more restrictive levels of care than would be predicted by their mild levels of ID.

Psychopathology and cognitive profiles may be associated with an individual’s genetic variant of PWS. Thus, research has shown behavioral differences between PWS due to paternal deletion and maternal UPD. Cases with deletions may show lower IQ, especially verbal IQ, and more frequent or severe problem behaviors, such as skin picking, hoarding, temper tantrums, overeating, and social withdrawal. Although a dampening of symptom severity is suggested in many UPD cases, there are occasional cases of more severe problems in UPD, primarily autistic-like features and relatively low IQ. In addition, persons with UPD may do better than their counterparts with deletions on verbal tasks but more poorly on visual-spatial tasks, including solving jigsaw puzzles. Indeed, although many persons with PWS are remarkably skilled in solving puzzles, this unusual strength seems to be limited to those with paternal deletions. The mechanisms that explain such differences in maladaptive behavior and cognition across genetic subtypes are unknown. In sum, many people with PWS are at increased risk for obsessive-compulsive, impulse control, and affective disorders. Yet even those who do not meet diagnostic criteria for these psychiatric disorders often show significant maladaptive behaviors that interfere with optimal adaptive functioning.

Down Syndrome. Occurring in approximately 1.2 in 1,000 live births, DS is the most common chromosomal abnormality leading to ID. It is most often the result of nondisjunction of chromosome 21. The syndrome has been the subject of considerable investigation.

More than 80 clinical features characterize the phenotype of DS, including cognitive impairments, hypotonia, facial dysmorphisms, congenital heart disease, and other anomalies. Studies of children with DS have shown distinctive cognitive and linguistic profiles. Notable strengths have been highlighted in visual versus auditory processing. Language impairment can be extensive, with particular difficulty in expressive language, grammar, and pronunciation.

In contrast to the relative overall weakness in the cognitive arena, persons with DS are often described as being particularly socially adept. However, studies of adaptive functioning suggest that these skills are not uniform, with communication scores trailing behind measures of daily living skills and socialization. The stereotype of a “Down personality” as being happy, good-tempered, affectionate, placid, and stubborn has been difficult to verify.

Compared to others with ID, persons with DS appear to suffer less often and less seriously from psychopathology. Adults with DS appear to be somewhat less prone to psychiatric disturbance than controls. This trend seems to extend to children and adolescents as well, in whom rates of psychiatric and behavioral problems are greater than in the general population but appreciably less than in other groups with ID. Commonly noted problems include difficulties with attention, impulsivity, hyperactivity, and aggression. In contrast to these problems, depression seems to be less common among children and adolescents than expected norms, although some youth appear to become increasingly withdrawn in their adolescent years. For many, this shift toward increased withdrawal seems gradual and subtle, and it may be an early harbinger of a later onset of depression or dementia in the adult years. Autism spectrum disorder appears to be relatively rare.

Williams Syndrome. First identified in 1961, Williams syndrome is caused by a microdeletion on chromosome 7 that includes the gene for elastin, a protein that provides strength and elasticity to certain tissues such as the heart, skin, blood vessels, and lungs. The condition affects 1 in 7,500 individuals, and persons with Williams syndrome often show hyperacusis, hypercalcemia, neuromusculoskeletal and renal abnormalities, and characteristic facial features described as elfin-like, cute, and appealing. People with Williams syndrome also typically show cardiovascular disease, especially supravalvular aortic stenosis, and these problems are likely associated with elastin insufficiency.

Apart from these medical issues, recent attention has focused on the interesting, possibly unique, cognitive-linguistic profile shown by many persons with this syndrome. Children with Williams syndrome show relative strengths in verbal short-term memory and language, and that in general verbal and nonverbal abilities develop at different rates for children with Williams syndrome (Jarrold et al., 2001). Indeed, for many years it was thought that these children might even perform at chronologic-age levels on a variety of linguistic tasks. Although age-appropriate performance in language has now been found in only small percentages of children with Williams syndrome, these children nevertheless show relative strengths in language (vocabulary, grammar, and short-term auditory memory), as well as in auditory processing and in some areas of music. In contrast, many children with Williams syndrome perform especially poorly on a variety of visuospatial tasks.

Studies have yet to fully examine the personality or psychiatric features of people with Williams syndrome. Early descriptions of people with Williams syndrome hinted at a “classic” Williams syndrome personality, described as pleasant, unusually friendly, affectionate, loquacious, engaging, and interpersonally sensitive and charming. Such qualities may change over the course of development, with adults being more withdrawn and less overly friendly than children.

Relative to controls, adolescents and adults with Williams syndrome appear more likely to initiate interactions with others, to enjoy social activities, to be kind-spirited and caring, and to empathize with others’ positive feelings or when others are in pain. At the same time, however, they appear to have difficulty in making or keeping friends and risk of “stranger danger.” Indeed, although sociability in Williams syndrome has generally been viewed as a strength, these features also seem to reflect the type of social disinhibition that is characteristic of people who are anxious, impulsive, and overly aroused. In fact, ADHD and anxiety including specific phobia and generalized anxiety are commonly co-occurring in children with Williams syndrome.

Smith–Magenis Syndrome

Bryan was a 19-year-old young man with moderate intellectual disability and a history of psychiatric issues including impulsivity, aggressive behaviors, and a striking history of self-injurious behaviors such as self-hitting, skin-picking, and pulling out fingernails and toenails. He had been given a diagnosis of autism. Bryan had restricted language abilities but got his basic needs met using a small set of phrases and gestures, though his speech was hard to understand and muffled. He lived at home among a devoted family including his parents and elder brother, and participated in a transitional school program, where he was segregated in a classroom for children deemed “lower functioning” with “behavioral needs.” Bryan and his parents visited clinic with the aim of finding a better medication regimen that might be able to support his adaptive functioning, articulating their “dream” that their son might one day live independently or participate more easily in social activities.

At the evaluation, Bryan’s medication regimen consisted of extended-release dexmethylphenidate, trazodone, buspirone, risperidone, and sertraline, with as-needed lorazepam and additional risperidone for agitation and aggression. These medications were not fully controlling his psychiatric symptoms. A careful history was taken, which elicited a history of infantile feeding difficulties, hypotonia and failure to thrive, and a striking pattern of lifelong sleep disturbance. Bryan fell asleep successfully, but woke every night around 2 to 3 a.m., did not go back to sleep, and was sleepy in the afternoons. He was noted to have somewhat heavy and coarse features with brachycephaly and prognathism. Accordingly, first-line genetic testing for intellectual disability consisting of chromosome array and fragile X was sent, revealing a 3.5-Mb interstitial deletion of chromosome 17p11.2, consistent with a diagnosis of Smith–Magenis syndrome (SMS). SMS is a genetic syndrome with a prevalence of 1:15,000–1:25,000, with disruptions to the *RAI1* gene (located within the deletion) accounting for the majority of features. A number of important studies support the presence of distinctive disruption to melatonergic control of the sleep cycle in SMS and the use of melatonin and beta-blockers to normalize sleep, with resultant improvement in behavioral and cognitive function. Bryan was started on melatonin 3 mg in the evening and propranolol 10 mg in the morning. Over 2 months, these were increased to final doses of 5 mg and 20 mg, respectively. His overnight sleep period increased from 4 hours to 8 hours, and by the conclusion of the titration, his self-injury was reduced by 90%, and aggressive behaviors stopped. He began to exhibit new learning, such as starting to search for and complete crossword puzzles, and he displayed an increased interest in social interaction and improved attentiveness. His psychiatrist was able to eliminate the use of risperidone, trazodone, and all as-needed medications. Importantly, standard-of-care recommended medical screenings for SMS were completed, revealing that Bryan was deaf. He received bilateral hearing aids and speech therapy and began to speak more. A year later, Bryan’s adaptive function was significantly improved, and he was able to transition to a supported group living situation with two male peers and began work at a part-time job.

Smith–Lemli–Opitz Syndrome

Brianna was a 13-year-old young woman carrying a diagnosis of intellectual disability and Smith–Lemli–Opitz syndrome (SLOS). SLOS is a congenital syndrome characterized by growth retardation, microcephaly, and multiple malformations, including a distinctive facial appearance. Most affected individuals have moderate to severe intellectual disability, but some have normal development, and it is increasingly thought that the disorder and carriers may be much more common than previously understood. In SLOS, mutations in the *DHCR7* gene result in derangement of cholesterol metabolism with elevated serum 7-dehydrocholesterol (7DHC) and low serum cholesterol. Affected individuals almost always display a variety of structural midline and para-midline brain findings, most commonly abnormalities of the corpus callosum. Sterol levels display a strong correlation with MRI brain findings and the degree of somatic malformations, supporting a link between altered cholesterol/sterol metabolism, deficient brain myelination, and changes in neurotransmitter function that may underlie the neuropsychiatric phenotype.

SLOS is, therefore, a specific etiology resulting in intellectual disability, as well as a disorder that may be simultaneously conceptualized as being a biochemical genetic disorder, multiple congenital anomaly syndrome, and/or brain malformation. As with many metabolic disorders, it is thought that dietary supplementation of the deficient substrate, in this case, cholesterol, may support ongoing brain development. Brianna received cholesterol supplementation since diagnosis and ongoing dietary optimization, as well as support for learning via an Individualized Educational Plan at school. She received low-dose trazodone to support sleep fragmentation; however, as she entered her teenage years shortly after puberty, Brianna began to exhibit increasing challenges with cognitive control and behavioral dysregulation, becoming much more aggressive towards caregivers and peers and with self-injurious behaviors. Simultaneously, she talked of visual and auditory hallucinations, particularly centered around seeing, hearing, and interacting with a person called “Cassie.” These phenomena waxed and waned somewhat on a multiweek or monthly basis, but generally, periods of increased aggressive behaviors coincided with what was interpreted as perceptual or psychotic phenomena.

Olanzapine was started to address aggressive behaviors, self-injury, and presumed psychosis and was titrated to 10 mg twice per day. Brianna’s aggressive behaviors declined somewhat, but the perceptual phenomena appeared unresponsive, and she gained some 40 lb. With concern for treatment resistance and weight gain, she was switched to haloperidol 5 mg twice per day. With the use of this agent, Brianna became more irritable with continuing hallucinations. At this point, the treating child psychiatrist sought consultation with a developmental neuropsychiatrist and biochemical geneticist at a specialist center. Laboratory studies revealed that 7DHC levels were elevated. In accordance with best practice guidelines for SLOS, both trazodone and haloperidol, which are contraindicated in this disorder due to their link with 7DHC elevation, were stopped. Brianna was started on valproic acid, which proved effective in reducing her behaviors and addressing psychosis. Melatonin was prescribed for sleep initiation difficulties with good effect.

DEVELOPMENTAL CONSIDERATIONS IN CHILDREN WITH INTELLECTUAL DISABILITY

Throughout the 20th (and now 21st) century, children with ID have been an ongoing topic of developmental research. Small groups of researchers have examined the development of various Piagetian cognitive domains, language abilities, social skills, and even morality. Besides providing information about basic milestones or natural histories, these studies aid in understanding the underlying processes of development. Researchers have been able to specify the ordering of development (sequences), the ways in which levels in certain areas relate to levels in other areas (cross-domain relations), and the points at which the speed of development (rate) changes. Such analyses are now being applied to children with different etiologies of ID. In addition, developmental analyses have extended beyond studies of children themselves. Many developmental psychologists examine mother–child interactions, family behaviors in families of different-aged children, and the child's interactions with peers, neighbors, and schools. This section examines both child-related and environment-related aspects of development in children with ID.

Child-Related Aspects of Development

Overview. Children with ID traverse the same sequences in their development as do children with typical development, but in the setting of certain forms of ID there are strengths and weaknesses not generally found in typically developing children. Children with ID also show particularly slowed development at certain ages and tasks, which seem related to specific types of ID, although the reasons for such slowings are the subject of ongoing research.

When examining child–environment interactions, it is found that mothers act “the same and different” compared to mothers of typically developing children at similar levels of functioning. Mothers of children with ID are similar in that they shorten their speech, focus on keywords, and in other ways, structure the environment for their child's development. They seem, however, to be much more didactic in their interactions. Families of children with ID also differ widely from one another. When the child with ID shows less maladaptive behavior, and when the parent's style of coping is more problem-focused, the result seems to be reduced levels of parent and family stress.

Sequences. Typically developing children show a specific, possibly universal, ordering to their development. For example, in Piagetian cognitive development, children proceed from sensorimotor, to preoperational, to concrete operational, to formal operational thought. Even within these four larger stages, smaller orderings prevail. Thus, within sensorimotor development, infants proceed in order through Piaget's six substages in each of several subdomains. Do children with ID also follow a “similar sequence” to their development? For the past 50 years, similar sequences have been found for a variety of children over many tasks: in almost 20 Piagetian domains, in symbolic play, and in linguistic grammar and pragmatics. Similar sequences even hold for those children with genetic or other organic causes for their ID. The only possible exceptions include some children with uncontrollable seizures (where accurate testing is difficult) and some children with autism, who may show different orderings due to their particular disabilities on certain social tasks. For almost all children and for a wide variety of behaviors, development for children with ID proceeds along similar sequences to those found in typically developing children.

Cross-Domain Relations. If children with ID proceed in the same developmental ordering as do typically developing children, might they also show the even or flat profiles that groups of typically developing children show from one domain to another? Such a “similar structure” to development was proposed by Zigler in the late 1960s. Contrary to similar sequences—which hold for all children with ID—cross-domain structures may differ based on which group one considers. With a few exceptions, children with cultural-familial ID do show even or near-even performance across various intellectual domains. In contrast, children with different organic forms of ID show specific intellectual strengths and weaknesses. For example, three separate groups show weaknesses in sequential (or bit-by-bit, serial) processing compared to simultaneous (i.e., gestalt, holistic) processing. Such sequential deficits are found in boys with FXS, children with PWS, and children with Smith–Magenis syndrome. Children with DS may have particular weaknesses in expressive versus receptive communication and specific problems in grammatical abilities. Children with Williams syndrome show greater deficits in visuospatial processing skills, and a subset of these children shows heightened abilities in language. Different etiologies of ID, then, show different characteristic intellectual strengths and weaknesses.

Developmental Rates. A further issue concerns a child's rate of development. Children with ID develop at slower rates than typically developing children. As noted in the Prevalence section, nonspecific or mixed groups show reasonably steady rates of development, as shown by stable IQ after the early childhood years. Children with different types of ID, however, may have periods of accelerated or slowed development, and these periods seem to be related to either age or task difficulties. For example, boys with FXS show stable developmental rates until the age of about 9 or 10, at which time development slows. Similarly, in DS, both cross-sectional and small-scale longitudinal studies show that these children slow over the 6-to-11-year period. Throughout this age span, children with DS slow in their development of linguistic grammar, intellectual skills, and adaptive behavior. In both FXS and DS, it remains unknown why such age-related slowings occur, whether all children with these disorders show such slowings, or if slowings are seen across all domains.

A second type of slowing relates to pronounced difficulties in mastering a specific developmental task. These can occur at a variety of ages, whenever children with a particular type of disability reach a specific developmental task. Consider young children with DS (who also show age-related slowing from 6 to 11 years). These children show difficulties in acquiring certain tasks of infant intelligence, even after accounting for their already slower rates of development. Later, toddlers with DS show increasing delays in expressive as opposed to receptive language skills. As a result of both age- and task-related slowings, then, children with DS generally show their highest IQ scores during the first year of life, after which IQ declines.

Contextual Aspects of Development

Mother–Child Interactions. Following research on interactions between typically developing children and their mothers, mother–child interaction studies in ID began during the mid-1970s. This research has shown that mothers of children with ID are both similar and different in their interactions than mothers of typically developing children of the same mental age (MA). Specifically, the two groups of mothers behave similarly on what might be called the structural aspects of behavior. In language, for example, mothers shorten their speech, simplify their vocabularies, raise their pitch, repeat key words, and generally provide the “motherese” typical of mothers of typically developing children. As a result, mothers of typically developing 2-year-olds act almost identically to mothers of children with ID who are at 2 years MA.

However, compared to mothers of typically developing, MA-matched children, mothers of children with ID are oftentimes more didactic. They more often initiate the topic of interaction, take longer speaking turns, talk at the same time as their child, and in other ways control the interaction. As a result, the child is allowed fewer opportunities to initiate and control the conversation. It remains unclear why such stylistic differences occur. The prevailing view holds that mothers of children with ID are worried about their child’s development: in their zeal to teach and instruct their children, these mothers might inadvertently be using a style of interaction that is not the most effective. Although only a few studies exist to date, young children with ID seem to develop faster when their mothers are less intrusive. A recent study examined mother–child and father–child interactions in 89 children with ID ranging from 20 to 47 months (Vilaseca et al., 2019). Results indicated that maternal responsiveness and paternal teaching predicted cognitive development. These studies provide evidence of the importance of paternal involvement and maternal responsiveness for cognitive and language development in children with ID.

Family Reactions. Over the past few decades, family studies in ID have changed enormously, from a predominantly negative to a more balanced perspective. Before the early 1980s, families of children with ID were perceived to be families in crisis. Mothers were examined for their “mourning” reactions, couples for divorce, and mothers, fathers, and unaffected siblings for the presence of depression and other forms of psychopathology. Since the early 1980s, however, family researchers began to change how they conceptualized families of children with ID. From an earlier focus on family pathology, researchers now saw families of children with ID as families facing increased stress. And while children with ID might add stress to the family system, now researchers understood that this stress could result in negative or positive adaptations. This changing view implied a more normative view of these families: just as every family faces a variety of stressors in life (e.g., illness, loss of job, etc.), so too do families of children with ID.

The move from a negative to a stress-coping perspective also has other implications. First, it allows for a change away from a predominantly “between-group” research strategy. Previously, most studies compared families of children with disabilities to families of typically developing, nondisabled children of the same chronologic or mental age. Now the between-group focus has been complemented by within-group studies. Given that families of children with ID vary in their ability to cope, what causes better adjustment in one family and worse adjustment in another? What child, parent, or family characteristics foster better adaptation? To date, most work has examined child characteristics such as the child’s age and degree of impairment. For both variables, findings have been inconsistent. Some studies find it more stressful to parent older children with ID, and some suggest that families may experience more stress when the child begins puberty (11 to 15 years) and again when the child reaches early adulthood (20 to 21 years). However, other studies do not find such relations between increased family stress and the child’s age. Similarly, some studies find that it is more difficult to parent children with more severe levels of disability, whereas other studies do not.

Another characteristic that has been examined is the child’s degree of maladaptive behavior. So far, strong connections have been found between child maladaptive behavior and family stress in families of children with mixed etiologies, with PWS, and with 5p- (cri-du-chat) syndrome. Less clear is why such connections occur. Although most researchers feel that child maladaptive behavior leads to increases in familial stress, increased familial stress may also elicit more child behavioral problems. In studies of parent coping style, parents who more actively, constructively attempt to manage their child do better than those parents who adopt a “palliative” coping style, one that either dwells on or ignores parental emotions. This difference in coping style may help buffer parents and families from the increased stresses of parenting a child with ID.

Psychopathology in Intellectual Disability

Developmental disability is a significant risk factor for psychopathology in general, and, as may be inferred from the description of causes above, this increased risk may derive from biologic vulnerabilities as well as risks that accrue from the environment. Moreover, individuals with IQs below 70 have a two- to fivefold higher rate of psychiatric disorders overall compared with typically developing persons. A host of explanations, highlighted in Table 39–9, have been put forward in efforts to account for this added risk. Included are developmental experiences with which these individuals must contend, including perceived rejection from peers and frustration from parents. The repeated experiences of failure or difficulty achieving what appears to come naturally to typically developing peers, the recapitulation of experiences of failure with each developmental stage, and less well-developed or perhaps less supportive peer groups all take a toll on ego development. In addition to specific biologic vulnerabilities, the common comorbidity of ID with physical illness, for example, epilepsy, may also increase the risk of mental illness.

Table 39–9.
Possible Contributions to Increased Vulnerability to Mental Disorders in Persons with Intellectual Disability

Neuropathologic process(es) responsible for intellectual disability may also cause or increase the risk for mental illness.
There may be an increased likelihood of loss and separation, particularly in out-of-home placements.
Communication deficits may predispose to emotional/behavioral disturbance.
There is vulnerability to exploitation and abuse by others.
There may be inadequate coping skills.
Family stress may be heightened in the presence of a child with developmental disability.
There is a risk of a limited network of social relationships and repertoire of social skills.
There is a risk of reduced opportunities for the development and exercise of recreational and occupational skills.
There is a possible adverse effect of the disability on self-esteem, and possible dysmorphology.

Moreover, the treatments for epilepsy and other medical conditions may carry some “behavioral toxicity” which can increase the likelihood of diagnosed mental illness. Phenobarbital was widely reported to increase the risk of motoric hyperactivity and disinhibition in children and in individuals with developmental disorders, and phenytoin may cause “cognitive toxicity.” While neither of these agents is used as frequently today, similar concerns may obtain for essentially any of the medications that are used for the management of epilepsy or other chronic medical conditions.

In general, individuals with developmental disabilities may experience the full range of mental illnesses as occur in the general population. A meta-analysis of epidemiologic studies of psychiatric disorders in individuals with ID revealed higher rates of psychiatric disorders in children with versus without ID, and higher rates in children and adults with more severe forms of ID versus milder forms (de Ruiter et al., 2007). However, evidence of a greater prevalence of psychiatric disorders in adults with *mild* disability as compared to adults in the general population is less clear. Other studies have shown that, in children, there is evidence that the developmental *course* of psychopathology is similar from ages 6 to 18 for children with and without ID. For instance, in general, internalizing behaviors increase with age and externalizing behaviors decrease with age. Specific risk factors for psychiatric disorders in children with intellectual impairments include both family and child characteristics: moderate versus mild levels of intellectual impairment, adaptive behavior deficits, poor socialization, language impairments, living with one biologic parent, and low family SES.

In 2007, the National Association for the Dually Diagnosed (ID and mental illness), in collaboration with a number of other professional organizations, published a manual to assist clinicians in psychiatric diagnosis with this population. The DM-ID provides a number of explicit examples of adapted diagnostic criteria for each diagnosis and is currently under revision. Additional specific psychiatric disorders as they appear in individuals with ID are reviewed below.

Attention-Deficit/Hyperactivity Disorder. The rates of ADHD in ID are estimated to between 9% and 18%. Although considerable research has been done on the treatment of ADHD, virtually all of these studies have specifically excluded children with ID. Moreover, the diagnosis of ADHD is based upon developmental considerations, namely, hyperactivity, impulsivity, and inattention significantly greater than that expected for a given developmental age, and thus the threshold for diagnosis in persons with severe to profound ID should be elevated.

For persons with ID, the diagnosis of ADHD is qualified as being excessive for an individual’s *mental age.* In the context of profound ID, attention span, distractibility, or “on-task” behavior are predictably quite variable. Individuals given the diagnosis of ADHD in this context should, in comparison to their peers with similar levels of intellectual impairment, exhibit unusually short attention span, excessive psychomotor activity level, remarkable impulsivity, and so on. In many cases, the clinician will encounter a situation in which an individual does not evidence remarkable psychomotor activity or attentional difficulties but may be unusually impulsive. In these situations, one should entertain the diagnosis of an impulse control disorder. Such a diagnosis, for example, might be appropriate for an individual who inexplicably strikes out at a peer in the absence of any identifiable environmental stressor.

Impulse Control and Stereotypic Movement Disorders: Self-Injury and Aggression. Every effort should be made to determine and treat the underlying cause of SIB or aggression, not merely to suppress the behavior. However, in some cases, for example, stereotypic movement disorder with SIB, the symptom is essentially the diagnosis. Aggression and SIB are common in ID and increase with greater severity of cognitive impairment. SIB typically takes the form of chronic, repetitive, and frequently stereotyped behavior causing trauma. It occurs in the context of specific genetic syndromes, for example, self-biting in Lesch–Nyhan syndrome and fingernail pulling in Smith–Magenis syndrome, but also and more commonly in persons with unknown or nonspecific causes of ID. DSM-5 added specifiers to the diagnosis of stereotypic movement disorder for these situations.

In a review of psychiatric consultations in an institutional setting, it was reported that SIB was specifically cited as a reason for referral in 36% of the 251 cases examined. However, SIB as a presenting symptom is generally unhelpful in predicting the ultimate psychiatric diagnosis.

As SIB and aggression are nonspecific symptoms, one must take into account the presence or absence of a variety of factors to arrive at a presumptive diagnosis. Among these factors are the chronicity of the behavior, what function it serves, whether it is invariant in its topography (e.g., hitting only the right ear suggesting an ear infection), whether it is situational, whether it occurs in concert with regression from a previous level of function, and whether there are associated neurovegetative signs that correlate with its onset.

Oppositional Defiant Disorder/Conduct Disorder. The DSM-5 diagnosis of oppositional defiant disorder or conduct disorder also requires comparisons to others of similar MA. Further, both diagnoses assume some degree of deliberateness on the part of patients (e.g., disobedience motivated by spite or resentment), which can be very difficult to discern in nonverbal subjects with profound cognitive deficits. As such, there is a lower limit in terms of severity of ID below which the reliability and utility of these diagnoses becomes suspect and an unspecified disruptive or impulse control disorder is likely to be utilized for diagnostic purposes.

Anxiety Disorders. Specific anxiety disorders, for example, separation anxiety, obsessive-compulsive disorder, panic disorder, generalized anxiety disorder, and so on, rely heavily on an individual’s ability to describe the subjective symptoms of anxiety. Patients who are clearly avoidant, who exhibit autonomic arousal in the face of stimuli that most of their peers would not find aversive, who present with other features of anxiety but who cannot articulate their subjective states, might be given a diagnosis of unspecified anxiety disorder.

In some cases in which individuals engage in behavior that appears compulsive or driven, and for whom such behavior seems ego-alien, the diagnosis of unspecified obsessive-compulsive or related disorder might be considered. Oftentimes these patients engage in self-restraint (securing their extremities in their clothing) or cling to their parents or care providers, seemingly to prevent SIBs. Simple repetitive behaviors or the insistence on sameness that can accompany autism spectrum disorders should not be given a separate OCD diagnosis. However, it may be useful to organize treatment with an additional diagnosis beyond “autism” if, for example, the focus of treatment is a sleep disturbance, impulsive aggression, anxiety, or the like.

Although common, anxiety disorders appear to be underdiagnosed in persons with ID. The wide variability in prevalence rates, from 1% to 25%, is attributed to difficulty in making a diagnosis. Moreover, an individual with ID may not be able to identify subjective anxiety as an underlying cause of distress, and a patient's aggression or agitation may be suggestive of a disorder of impulse control rather than reflective of underlying anxiety. Indeed, common symptoms of anxiety in the population with ID include aggression, agitation, compulsive or repetitive behaviors, self-injury, and insomnia. Panic may be expressed as agitation, screaming, crying, or clinging, which may even appear as delusional or paranoid behavior. Phobias may also occur in this population and may even be more common in persons with developmental disabilities. Experienced clinicians have noted that persons with developmental disabilities are at high risk for abuse, thus placing this population at a greater risk for posttraumatic stress disorder (PTSD). With data suggesting that it may be seen in nearly 8% of the general population, PTSD is an important diagnosis to consider in individuals with ID.

Eating Disorders. Because of the reliance of diagnostic criteria upon subjective experiences, the diagnoses of anorexia nervosa and bulimia are effectively precluded for individuals with severe or profound ID. For example, one would be hard pressed to identify in nonverbal patients such things as classic distortions in body image, or guilt feelings associated with bingeing. Food refusal or self-induced vomiting would have to be viewed as atypical eating disorders if such symptoms were to occur in the absence of other diagnosable disorders (e.g., depression, rumination, etc.). Pica is perhaps the most common eating disorder among persons with ID.

Organic Mental Disorders. One could argue that everyone with ID has some “organic” cerebral dysfunction, and thus any psychiatric illness should be regarded as organic or due to a general medical condition. In his classic study of psychiatric illness in a sample of institutionalized patients with DS in the 1970s, Menolascino appropriately argued that psychiatric nosology did not have to be reinvented to accommodate individuals with a “tissue diagnosis.” Moreover, he reasoned that patients with the so-called “dual diagnoses” of mental illness and DS need to be distinguished from those with DS alone. Thus, the application of the diagnoses of organic mental syndromes and disorders is best approached as if patients do not have ID. The same principle should apply to personality disorders. The diagnosis of “organic” personality disorder is probably best reserved for individuals whose pre-existing personality was altered in a pathologic way by some additional cerebral insult. In essence, this category has more clinical utility if reserved for patients whose ID is acquired after a period of typical development, usually secondary to trauma experienced in childhood or early adolescence.

Psychosis. Patients with developmental disorders are at an increased risk for schizophrenia (approximately 1% prevalence rate in persons with ID), bipolar disorder, and other mental illnesses that may include symptoms of thought disorder and hallucinations. The diagnosis of schizophrenia requires, at least to some extent, that a patient communicate their experience of delusions or hallucinations. Thus, in individuals with profound ID with limited communicative ability, the diagnosis of classic schizophrenia is arguably impossible. Nonetheless, some individuals display presumptive evidence of response to hallucinations (e.g., striking or shouting at empty space, throwing imaginary peers from furniture) or adopt catatonic postures that can appear to be psychotic in origin. In these cases, the diagnosis of psychosis should be considered if these signs exist in the absence of sufficient evidence of a supervening mood disorder.

Mood Disorders. Even in profound ID, the diagnosis of mood disorders is fairly straightforward. In general, a change in mood from baseline is obvious (recent onset lability, tearfulness, mood elevation, irritability). If coupled with changes in interests, activity level, sleep, appetite, or sexual behavior, of sufficient duration and causing sufficient impairment in adaptive function, the diagnoses of mania or of depression can be made in nonverbal patients.

Mood disorders are not uncommon in persons with ID, although it is unclear from studies to date whether or not mood disorders present at higher rates than in the general population. As noted above, learning problems, social skills deficits, and low self-esteem are often associated with developmental disabilities and represent risk factors for the development of mood disorders. There are no striking differences between the expression of mood disorders in persons functioning in the mild and moderate range of ID and their typically developing peers. Differences may emerge among persons with severe to profound disability, but potential equivalents of mood disturbance may be recognizable, including irritability, crying, problems in sleep or appetite regulation, agitation, mood lability, social withdrawal, and isolation. Aggression or SIB may also be seen as behavioral manifestations of dysphoria in persons regardless of developmental level.

Other Disorders. The diagnosis of Tourette syndrome is difficult in persons with profound ID. Frequently, these individuals display stereotyped or other movements, and it can be challenging to discriminate intentional from unintentional movements or sounds, or to distinguish vocal tics from spontaneous, stereotyped, or echolalic vocalizations in individuals frequently incapable of functional speech. The diagnosis of stereotyped movement disorder might also be considered in such circumstances.

Since elimination disorders require an MA of 4 or 5 years in order to be considered, the diagnoses of functional encopresis or enuresis are seldom made in the context of severe ID. In some instances, individuals appear to lose previously acquired skills, for example, urinary continence, but such losses typically do not occur in isolation, suggesting alternative diagnoses (e.g., delirium, depression, etc.).

Somatoform disorders, depersonalization disorders, and sexual disorders are less frequently diagnosed in the context of ID, though certainly not precluded. Sleep disorders ultimately require the subjective input of the patient regarding the adequacy of rest, occurrence of nightmares, and so on. Given the frequent history of abuse reported for people with ID as a group, one should not overlook the possibility of PTSD when sleep disturbance is a presenting problem.

Provisional Diagnoses. In many cases individuals with ID may not clearly fall into a single diagnostic category. Comorbidity is common. Additionally, some individuals may have psychiatric symptoms that significantly interfere with habilitative function, but which do not allow for a clear distinction between certain diagnoses. It may be difficult to distinguish between an impulse control disorder, perhaps characterized by an individual who engages in impulsive aggressive acts, versus an anxiety disorder, suggested by an individual who strikes out in the context of a stressor that would go unnoticed by most people. The clinician should always make a best effort at a working diagnosis and be prepared to make modifications as indicated by data gathered through collateral sources and from increasing familiarity with a particular patient.

Approach to Maladaptive Behavior

As with psychiatry in general, there is little specificity that can be attached to a given symptom. Persons with ID will typically be referred for evaluation because of self-injurious, aggressive, impulsive, or hyperactive behavior. Because of the lack of diagnostic specificity for each of these symptoms, a diagnostic decision tree cannot be constructed. Instead, it is perhaps more useful to ask a series of questions about the expression of a particular behavior. If the behavior is of recent onset, one is more likely to consider an acute medical or psychiatric etiology. If the behavior is highly situational, occurring primarily in the context of the stress of task demands, the likelihood of a psychosis or mood disorder is probably reduced. If attempts are made to avoid the behavior by self-restraint, the inference of some ego-dystonic features may be tenable. Assessing the sum of these and collateral data will lead the clinician to a presumptive diagnosis that will form the basis for a treatment plan.

Diagnostic Instruments, Rating Scales

A number of diagnostic and behavioral rating scales have been developed for the population with ID. While neither diagnostic nor treatment decisions should be based entirely upon the results of a given instrument, the systematic collection of data through such scales is a very useful adjunct to the clinical diagnostic or monitoring process. Among the most common general behavior rating scales are the Aberrant Behavior Checklist (ABC) and the Developmental Behavior Checklist (DBC). The Behavior Problem Inventory (BPI) is particularly useful for self-injurious, aggressive, and stereotyped behaviors. The Diagnostic Assessment of the Severely Handicapped (DASH), the Reiss Screen for Maladaptive Behavior, and more recently the Reiss Scale for Children's Dual Diagnosis are all instruments whose primary utility is to poll for the presence of mental disorders.

TREATMENT

Prevention

Preventive treatment strategies for ID largely focus on specific medical interventions to reduce the prevalence of ID, and treatments that mitigate associated complications, for example, treating associated mental disorders. The merits of primary prevention are obvious, and the successes enjoyed with PKU should continue to provide powerful incentive for the ongoing collaborations of basic scientists and clinicians. Evidence suggests that newborn metabolic screening is extremely successful in reducing the incidence and severity of some ID syndromes (Brosco et al., 2006). The impact of other programs is less clear. For example, although folic acid supplementation appears to significantly reduce the risk of neural tube defects, and may also reduce the risk of autism, compliance with recommendations to increase *dietary* folate appears to be disturbingly low, although compliance with supplementation is as high as 80% (Pathirathna et al., 2020). Further, it appears that the prevalence of trisomy 21 is increasing despite the availability of noninvasive prenatal testing (NIPT); termination rates are unchanged or decreasing as compared to termination rates prior to NIPT. Finally, a recent review of trends in developmental disabilities in the United

States from 2009 to 2017 (Zablotsky et al., 2019) indicated a significant decrease in certain developmental delays but significant increases in ID, ADHD, and autism.

Influence of Etiologic Factors on Treatment

As suggested above, the approach to treatment begins with the diagnostic process. In some cases, the underlying cause of ID may be particularly important in considering treatments. For example, in ID associated with PKU, attempts have been made to minimize or to attenuate hyperactivity and impulsivity by dietary modification. As animal models of this disorder are developed and explored, it appears that dopaminergic abnormalities play a particularly salient role in the expression of maladaptive behaviors. Thus, early and continuous intervention with dopamine agonists plays a unique role in the treatment of behavioral and cognitive disturbance associated with PKU.

Abnormalities in serotonergic function have been reported in the context of DS. This hyposerotonemia led to trials of serotonin replacement with mixed results, but serotonergic drugs may yet hold relevance for persons with DS. In the context of PWS, serotonergic abnormalities are also being reported as responses to serotonergic agents. Taken together, the identification of the underlying cause of ID has become increasingly important in considering biologic treatments. In the same way, the diagnosis of mental disorders or syndromes in persons with ID will guide and influence treatment strategies.

TREATMENT OF MENTAL DISORDERS

Experience over the past decade has made it clear that ID is a multidisciplinary problem, and optimal treatment is multimodal. Biologic, psychological, social, and developmental dimensions should all be considered when designing a treatment plan for an individual with ID. Further, an integrative treatment approach should focus not only on ameliorating symptoms, but on restoring mental well-being, and caring for the family system as well. Typically, a treatment plan will include attention to psychoeducational, psychotherapeutic, and psychopharmacological interventions.

Psychotherapy

One should never assume that a person with ID cannot benefit from psychotherapeutic intervention simply because of their impairment in intellectual functioning. That being said, there are a number of potential barriers to effective psychotherapeutic treatment approaches, including limited verbal ability, cognitive flexibility, psychological mindedness, and self-efficacy. To overcome these barriers, certain modifications in approach are beneficial. It is important, for example, that an active therapeutic stance be employed, as well as concrete and supportive interventions and careful attention to the language abilities and developmental level of the patient in treatment. When these types of alterations are made, many patients with ID are clearly able to benefit. Specific psychotherapeutic approaches that have been shown to be effective include behavioral (in particular, applied behavior analysis [ABA] models), cognitive-behavioral, psychoeducational, and skills training (e.g., coping skills, social skills). Behavioral therapies are demonstrably effective in managing many maladaptive behaviors, particularly aggression and self-injury, in persons with ID. Interventions that should be considered include environmental modifications, caregiver education, and ABA. There is a large empirical evidence base for ABA, and recent attention has been paid to dealing with low–base-rate behaviors, improving generalization, and incorporating choice-making to improve outcomes. Typically, a behavioral assessment begins with a “functional analysis” of behavior or a detailed examination of the variables that reinforce or maintain behaviors. One considers the antecedent events and consequences of a behavior in question and typically must test hypotheses by systematically manipulating key variables. Matson and colleagues have shown that a checklist, called the Questions About Behavioral Function (QABF), can be used successfully to derive clear behavioral functions for most individuals (84%) across target behaviors of self-injury, aggression, and stereotypy. Further, when the results of the functional analysis informed the behavior program, subjects improved significantly more than those whose behavior programs were more generic. While screening instruments may thus be quite useful in beginning to identify reinforcing variables for maladaptive behavior, the development and implementation of an effective behavior program are best conducted by a behavioral psychologist or board-certified behavioral analyst (BCBA). In addition to behavior therapies, there is some evidence for the use of cognitive-behavioral therapy to treat depression in individuals with mild ID. Skills training approaches, such as teaching individuals with ID brief relaxation techniques, may be useful in reducing anxiety even in the context of moderate to severe ID. Parent skills-training approaches have been shown to improve developmental, behavioral, and family outcomes. Supportive groups for parents and siblings (e.g., SibShop) may also be of particular benefit. Family therapy can be particularly useful and provides a setting for education, support, and for consolidation of behavioral treatment and other interventions.

An important area of current research is to examine not only efficacy but also service delivery. A recent review of a range of psychosocial interventions (behavior analytic, cognitive training and rehabilitation, and parent training interventions) delivered by nonspecialist care providers shows that interventions delivered in this way do produce good outcomes compared to no treatment or treatment as usual. This finding is critical given the scarcity of specialists in rural and low-resource areas and countries.

Pharmacotherapy

There is a relative paucity of controlled clinical drug trials that include persons with ID, particularly individuals with the most severe cognitive impairment. As a result, clinicians must generally extrapolate from the general population with regard to pharmacotherapy in persons with ID. While studies remain limited, some emerging evidence suggests that individuals with ID may experience benefits and side effects of certain classes of medications differently than individuals without ID, and individuals with ID may require relatively unique dosing strategies. Additionally, drug–drug interactions should be considered prior to a new medication trial that may affect the availability or effectiveness of concurrent medications. Multiple psychiatric problems are common in individuals with ID and as a result, polypharmacy is common. Target symptoms, along with associated data on baseline severity, frequency, and duration of such behaviors or symptoms (preferably from evidence-based objective scales or measures), should always be clearly identified before starting a medication. Regular monitoring for side effects should occur after initiating medications and adherence to treatment reviewed before increasing dosages. Studies are also making it clear that genetic copy number variants associated with both loss of function and gain of function may be associated with some ID syndromes. As these data inform more personalized or targeted treatment approaches, it is likely that some medications will emerge as being specifically beneficial or specifically contraindicated in certain ID syndromes relative to the general population.

Commonly Cited Target Symptoms and Conditions for Medication Use

AGGRESSION

Antipsychotics. Antipsychotic medications have long been used in persons with ID for indications including aggression, hyperactivity, disruptive behaviors, and self-injury. This is the most widely prescribed class of psychotropic medication for persons with ID. More recently, due to relatively common side effects, they are now being reserved for older children or adults for whom intensive behavioral interventions or other medication options have failed, but they remain among the most widely studied and utilized medications for aggression.

There is evidence to support the use of dopamine antagonists in SIB and aggression both in theory and in practice. Due to the availability of the atypical neuroleptics, use of first-generation antipsychotic medications have dramatically reduced in this population.

Numerous randomized controlled trials and open label studies appear to suggest moderate efficacy of risperidone in reducing aggression in children and adults with ID. While side effects have been generally tolerable, common adverse events can include extrapyramidal side effects including akathisia and parkinsonism, somnolence, headaches, gastrointestinal side effects such as constipation, and weight gain. Other studies have found significant improvement in aggressive behavior with aripiprazole compared with placebo and adverse effects have been generally tolerable. There exists a small number of studies reviewing olanzapine, quetiapine, ziprasidone, and clozapine involving people with ID (Roy et al., 2013). Most studies assessing antipsychotic medications, including those conducted by Research Units on Pediatric Psychopharmacology Autism Network, in ASD include children with comorbid ID, though these studies usually have not stratified efficacy results based on IQ. Notably, a study by Tyrer could not distinguish atypical or traditional neuroleptic antipsychotics from placebo for effects on aggression (Tryer et al., 2008).

Individuals with ID appear to be at greater risk of developing tardive dyskinesia than the general population, with recorded rates ranging from 18% to greater than 30% following chronic use of first-generation antipsychotics. There also appears to be some emerging evidence, along with expert opinion, that children with ASD may be particularly prone to adverse effects with certain psychotropic medications. However, spontaneous abnormal involuntary movements are not uncommon in this population which may confound some of this data. The more widespread use of second-generation antipsychotics in persons with ID have reduced the risk of tardive dyskinesia and extrapyramidal symptoms, as well as cognitive toxicity. Constipation, which is often associated with distress and agitation when unaddressed, should be monitored when starting antipsychotics especially those with anticholinergic properties.

Mood Stabilizers. There is ample evidence to support an antiaggressive effect of lithium salts in the context of ID. The side effects associated with this agent, particularly the cognitive dulling that is occasionally reported by some recipients without ID, should raise the threshold for the use of this agent in the setting of ID. Valproic acid and carbamazepine may help to reduce impulsive aggression, though some of this evidence appears to be extrapolated from studies of the general population. Other research has examined valproic acid and topiramate as adjunctive agents with positive results, but studies remain limited for use of non-lithium mood stabilizing agents in ID.

Selective Serotonin Reuptake Inhibitors (SSRIs). The existing evidence on the use of serotonin reuptake inhibitors for the management of aggressive problems in children and adults with ID is scant. Responses to the SSRIs are varied with some studies reporting favorable results while others show negative effects or worsening symptoms (Sohanpal et al., 2007).

Beta-Adrenergic Antagonists. Small studies and case reports utilizing beta-adrenergic antagonists have also been reported to be of use in the population with ID and developmental disorders. It is not clear, however, whether the mechanism is central or peripheral. A systemic review by Ward found 14 studies utilizing primarily propranolol for “problem behaviors” including aggression in ID, with doses of propranolol up to 340 mg (Ward et al., 2013). However, none of the identified studies were RCTs, and the efficacy of beta-blocker medications remains debatable.

ANXIETY AND MOOD DISTURBANCE

Antidepressants. Special considerations in the use of antidepressant medication in ID include the common medical comorbidities as noted previously. Tricyclic antidepressants (TCAs) in particular (e.g., clomipramine) must be used with the knowledge that the risk of lowering seizure threshold is relevant. Although this risk in the general population is in the order of 1 in 1,000, in individuals with ID this risk may increase to closer to 1 in 5. Cardiac anomalies are common in some ID syndromes, and the anticholinergic side effects of some medications may be particularly significant in persons with DS. Individuals with ID may require lower levels of antidepressant drugs than their normally developing peers, and disinhibition has been described even with typical antidepressant doses of the serotonin reuptake inhibitors. Constipation associated with the anticholinergic effects of some TCAs can cause significant distress which, in people with ID, may be expressed as sleep disorders, loss of appetite, agitation, and aggression.

There are some individuals—particularly a subgroup within autism spectrum disorder—who appear to exhibit extraordinary sensitivity to drugs of this and other classes. This sensitivity, when it occurs, is manifest by disinhibition, and may present as an increase in target symptoms at doses of medication that might otherwise appear quite standard. In this context, individuals may be converted to responders with significant dose reductions, for example, reducing a starting dose of fluoxetine or citalopram from 10 to 2 mg, daily. Moreover, it is increasingly the norm that initiation doses for SSRIs in this population are lower, and the rate of dose increase is slower, than for the general population.

Mood Stabilizers. Some anticonvulsant drugs may improve cyclical mood disorders and impulsive aggression. Valproate has probably been studied most in this regard. Similarly, there is evidence to suggest that in the setting of cyclical mood disturbance, lithium may also be helpful.

Anxiolytics. Although benzodiazepines are commonly prescribed in treatment for anxiety in the general population, there are unique concerns when they are used in the context of developmental disorders, particularly regarding the possibility of increased confusion, cognitive impairment, unsteadiness, and paradoxical excitement. Barron and Sandman reviewed disinhibition associated with benzodiazepines that occurred in 35% to 68% of an institutionalized intellectually disabled population as compared to controls. Nevertheless, alprazolam, clonazepam, and lorazepam are widely used for the treatment of acute anxiety, particularly that associated with procedures. Their use should be considered in the absence of evidence of previous abnormal responses to these agents.

On the other hand, recent findings from animal modeling of haploinsufficiency of the SCN1A gene (Dravet syndrome) by Catterall and colleagues suggest that activation of GABA(A) receptors with low-dose clonazepam improves behavioral and cognitive impairments in mice. There is growing interest in this mechanism in genetic conditions associated with ID.

Buspirone. Buspirone is another serotonergic agent that has been reported to be of benefit in some persons with developmental disorders. Ratey and colleagues reported the use of buspirone in an open trial in persons with diagnosed anxiety disorders manifested by aggressive behaviors and SIBs. A study by Verhoeven and Tuinier also explored buspirone in the treatment of anxiety in persons with ID, suggesting that this agent should be among those considered in treating this population. Moreover, advantages include a relatively benign side-effect profile, specifically the absence of common motor or cognitive toxicities, at doses that are used to treat anxiety.

SELF-INJURIOUS BEHAVIORS (SIBS)

SSRIs. Trials of serotonin reuptake inhibitors in clinical practice are increasingly common among patients with SIB. Favorable results have been reported for fluoxetine, paroxetine, sertraline, and trazodone in this regard but all reports involve small numbers of subjects. While clomipramine has been shown to be useful in a well-controlled study, due to its effect of lowering seizure threshold, clomipramine is generally not a first-line treatment for compulsive SIB in individuals with ID who may have comorbid epilepsy.

Antipsychotics. One retrospective review has suggested that atypical antipsychotics improve aggressive behavior but not SIBs (Ruedrich et al., 2008). Small studies exist for some neuroleptic options (e.g., risperidone, olanzapine) with some encouraging results. Small studies and case reports involving clozapine have also shown some reduction in SIB. However, the literature involving antipsychotics for behavioral problems is generally lacking in outcome measures specific to self-injury. Although suggested by some, there is no convincing evidence that the mechanism of action of antipsychotics in SIB (or aggression) is merely to suppress behavior generally through a nonspecific sedating effect. Such an outcome is clearly undesirable in an individual with pre-existing cognitive impairment, and many of the earliest reports specifically note the absence of sedation.

Mood Stabilizers. There is evidence for the use of Lithium both as a monotherapy and concurrently with other psychotropics in reducing SIB. However, the risks of side effects and monitoring requirements may restrict use of this medication. Less evidence appears to exist for other options including valproate and topiramate though both have been studied with reductions observed in adult patients with ID.

Opioid Antagonists. Some individuals who self-injure appear to have altered pain sensitivity, as was suggested nearly a century ago by Ireland. This observation, coupled with data indicating that opioid antagonists can attenuate stereotypy and self-injury in animal models and data indicating that opioids may modify the function of dopaminergic systems, has fueled interest in this class of drugs. Naltrexone is the opioid antagonist most widely used for SIB, but the literature thus far is mixed. A 2013 Cochrane Review found some evidence of positive results for the indication of SIB in ID, but evidence was not conclusive (Rana et al., 2013). On balance, naltrexone appears to be well tolerated in persons with developmental disorders and IDs, with sedation as the side effect most likely to be observed.

NMDA Antagonists. A growing appreciation exists for the potential therapeutic utility of drugs acting at glutamate receptor subtypes. Glutamatergic and dopaminergic interactions in the neostriatum are the focus of research on the pathogenesis of a host of neuropsychiatric illnesses, including schizophrenia, obsessive-compulsive disorder, SIB, and aggression.

Dextromethorphan, an antitussive agent that also binds to the *N*-methyl-D-aspartate (NMDA) receptor, was reported by Welch and Sovner to have markedly attenuated SIB in a 25-year-old individual with congenital rubella syndrome. The patient was maintained on dextromethorphan for 16 months with sustained benefit. It is surprising and perhaps ominous that no follow-up studies have been reported with this drug in SIB. Lamotrigine is an anticonvulsant drug that also appears to antagonize glutamate by reducing its release. A recent case report suggested that lamotrigine may also be useful in reducing self-injury in the context of a stereotyped movement disorder.

Others. SIB and aggression can also dramatically improve with the withdrawal of phenobarbital. The potential behavioral “toxicity” of this and any drug should not be overlooked in designing treatment strategies for persons with ID. Moreover, medical comorbidity is the rule in individuals with developmental disabilities, and the importance of identifying and treating underlying medical problems or refining that treatment cannot be overstated.

OTHER OBSESSIVE OR COMPULSIVE BEHAVIORS. Of interest, there is some experience with a small number of persons with PWS treated with the anticonvulsant topiramate whose skin-picking behavior improved. The mechanism underlying this effect is unknown, and it might even involve peripheral effects of the drug, for example, on sensation, or perhaps even rate of wound healing. For PWS, obsessive-compulsive disorder occurs more commonly than in the general population, and compulsive skin picking may improve along with other compulsive behaviors with an SSRI.

SLEEP DISTURBANCE. Sleep disturbance is a little-studied but often significant problem for many persons with ID. Jan prescribed melatonin openly to children with moderate to severe ID of mixed etiologies. The children ranged in age from 1 to 11 years. All but two of the children were characterized as dramatic responders based on measures of hours of sleep, nocturnal awakenings, delayed sleep onset, and early-morning awakening. Melatonin was administered as a single 3-mg dose 1 to 2 hours before target bedtime each night. Pillar and colleagues also administered a single 3-mg dose and monitored sleep efficiency, as well as activity via wrist actigraph, in their sample of five children (3.5 to 13 years old) with severe ID. Sleep was significantly improved in the subjects receiving melatonin, and two of the subjects were still receiving melatonin up to 18 months after the completion of the study. This preliminary evidence suggests that melatonin deserves broader consideration for the treatment of children with ID and disturbed circadian rhythm of sleep.

SEIZURE DISORDERS. Crawford and colleagues performed an open-label but randomized, parallel-group, multicenter, add-on study comparing gabapentin with lamotrigine in 109 patients with treatment-resistant focal epilepsy and ID (Crawford et al., 2001). Subjects in both the gabapentin and lamotrigine groups experienced a reduction in seizure frequency by nearly half. Both drugs were equally well tolerated. Gabapentin may have had an edge with respect to some behavioral indices, denoted by the investigators as communication, cooperation, and restlessness, but lamotrigine also was credited with improving challenging behavior. Thus, both medications may hold promise for persons with ID and treatment-resistant epilepsy, and their effects on behavior should be the focus of additional study.

A larger study in which lamotrigine was added to the anticonvulsant regimen of children with ID suggested that those with autism experienced gains that could not readily be attributable to better seizure control alone. A recent double-blind, placebo-controlled trial of lamotrigine in autism, however, did not demonstrate significant results.

ADHD AND DISRUPTIVE BEHAVIORS. Despite reports of paradoxical responses to stimulant medications in persons with ID, with higher-than-expected rates of emergent motor tics and emotional lability, a growing body of literature supports the use of stimulant drugs for the treatment of ADHD in the context of ID. The available literature appears to suggest that overall, the effect size of methylphenidate in children with ID is lower than in children without ID. A higher dose of methylphenidate may be associated with a higher rate of adverse effects. Significant adverse effects include sleep difficulties, poor appetite, weight loss, irritability, social withdrawal, and increased motor activities including tics. A problem awaiting additional study concerns the likelihood of a response to stimulants in relation to the severity of cognitive disability. Data are mixed with respect to whether IQ negatively or positively predicts treatment response.

Atomoxetine is a nonstimulant that is used for similar target symptoms in the general population. There are no studies specifically examining its effectiveness in ID, but growing evidence suggesting that in autism spectrum disorders, atomoxetine may be useful for target symptoms of inattention, hyperactivity, and noncompliance/oppositionality.

An open trial of the use of amantadine in children with various developmental disabilities and disruptive behaviors was quite promising. A subsequent small multisite, controlled trial in children with autism yielded mixed results. Memantine has also shown promise in open trials for agitation in the context of autism.

Considerable evidence is accumulating to support the effectiveness of risperidone in treating severe disruptive behavior in children and adolescents with cognitive disability. Sedation and weight gain were the most common side effects. Similar studies exist for aripiprazole, although both controlled trials were sponsored by the manufacturer. A 2017 Cochrane Review found a lack of evidence to support the use of quetiapine, ziprasidone, or any other atypical antipsychotics besides risperidone for disruptive behavior disorders in children and youth and no evidence for children under 5 years of age although this review was not specific to children with ID.

COGNITION. There is no evidence that medications, nutritional supplements, or other theorized nootropics have demonstrated improved cognition in ID. However, there are a growing number of strategies emerging from animal model and genetic identification studies that may eventually redefine this class of therapeutics for the population with ID. Some early studies suggest possible enhancement of cortical plasticity in animal models for fetal alcohol syndrome. Medications with indications for major neurocognitive disorders, such as acetylcholinesterase inhibitors, do not have evidence for use in ID. The efficacy for various nutritional supplements, though sometimes popular in practice, has not been well established in clinical trials. For example, a randomized controlled trial of antioxidants and/or folinic acid for infants with DS found no evidence of cognitive benefit. Another randomized controlled trial found no evidence of cognitive benefit for a popular synthetic supplement piracetam in children with DS but did find numerous adverse effects. Even as some novel treatments progress to clinical trials, the question as to whether there are particular developmental windows for therapeutic effectiveness remains important to address.

Services and Supports

In contrast to even 20 years ago, individuals with ID can now access a wide variety of services. These services can be found throughout the United States and last throughout the lifespan; see Table 39–10 for a listing of some of these services.

Early intervention and educational services became widespread following the passage of PL 94–142 (the Education for all Handicapped Children Act of 1975); this legislation has recently been extended and modified by IDEA, the Individuals with Disabilities Education Act (IDEA) of 1990, with amendments in 1997 and 2004.

Early Intervention. The IDEA part C provides federal grants to states to provide early intervention services for young children from birth until a child’s third birthday. Such services are provided by different “lead agencies” coordinating in each state and as a result services may vary widely between states. For instance, in some states, birth to 3 (B-3) care may begin with early intervention specialists providing services, such as speech and language therapy, in the child’s home, while in other states B-3 care can also entail center-based services. Once the child is preschool age, most services are provided through the public school district. These services are center-based and include both one-on-one therapies and small group education services. B-3 and preschool services focus on multiple domains of functioning, including cognitive development, language, motor, social, and adaptive functioning.

With the passage of Part H of PL 99–457 (the Education of the Handicapped Amendments of 1986) early intervention services have increasingly emphasized the family's role. Under IDEA, agencies are required to develop an Individualized Family Service Plan (IFSP) for each child and family receiving early intervention services, focusing on family strengths and needs in caring for their young child with ID. An IFSP is similar to an Individualized Education Program (or Plan), called an IEP (see below), in that both contain goals that are regularly monitored and updated as goals are reached, and new goals are written. Unlike an IEP, however (1) Eligibility for early intervention as per Part C of IDEA is determined by state eligibility criteria (which are variably defined) and is often different from eligibility for special education under Part B of IDEA; (2) The IFSP includes both child and family goals and objectives as opposed to an IEP which is focused on the individual student; (3) IFSP includes services to help a family in natural environment settings, not just in daycare/preschool, but at home and in the community; (4) The IFSP includes services to help a family in vivo in the child's natural environments in the home or community as opposed to solely school environments; (5) The IFSP team involves a service coordinator who assists the family whereas students with an IEP have a case manager, usually a special educator at the school.

Table 39–10.
Service Needs and Resources for Families of Children at Different Ages

	Needs	Resources
Ages 0–3 years		
Child	Evaluation: physical, motor, cognitive, linguistic, social-emotional; early intervention services	Multidisciplinary evaluation, which results in an individualized family service plan (IFSP), with child and family receiving either center- or home-based early intervention services for set number of hours per week
Mother	Emotional support, caretaking behaviors	Support groups by disability, region, and etiology; part of early intervention evaluation, intervention, and IFSP
Family	Support, financial assistance, information	Support groups; depending on the problem, state developmental disabilities or insurance payment for some services; hospitals, agencies, groups
Ages 3–21 years		
Child	Evaluation, referral, and individualized education program (IEP)	School system: involves legal process of evaluation and placement (notification, hearings, appeals if necessary); information on “transition” to adult services as child nears

		age 21 years (and school services end).
Family	Information, financial assistance, support	Local and national groups; departments in some states, including respite care, camps, art (Very Special Arts) or athletic activities (Special Olympics), scholarships for adolescents with some disabilities (deafness, blindness)
Older than 21 years		
Offspring	Residential services, work	Run by state developmental disability departments; parents and offspring have major say concerning whether residential or work placements are appropriate.
Family	Support, information, guardianship issues	Continuation of many of the services provided during the school years, particularly for individuals with severe disabilities, provisions for residential and work status after parents can no longer serve as offspring's legal guardians

Reprinted with permission from Hodapp RM. *Development and Disabilities*. Cambridge University Press; 1998:196.

School. From ages 3 to 21, specialized education services are provided through local school districts. The IDEA requires that public school systems serve all children with disabilities and outlines the procedures and legal provisions to do so (see Table 39–11). This process includes an assessment of the child’s academic performance, social/behavioral functioning, and adaptive functioning, and provides annual goals and instructional objectives. The IEP is the result, a legal document that binds the school district to provide the services described in the IEP. Educational services have become a right—not a privilege—for parents of children with intellectual and developmental disabilities.

Table 39–11. Summary of IDEA

Major Provisions	Description
Zero Reject Policy	▶ Schools must educate all children with disabilities (see covered disabilities in Table 39–12) ▶ A state's education agency is responsible for locating, identifying, and evaluating all children, from birth to age 21, who are suspected of having disabilities (**child find system)**
Nondiscriminatory Identification and Evaluation	▶ Schools must use nonbiased, multifactored methods of evaluation to determine whether a child has a disability and whether special education is needed. ▶ **Protection in evaluation procedures:** evaluation procedures must not discriminate on the basis of race, culture, or native language.
Free, Appropriate Public Education (FAPE)	▶ All children with disabilities must receive a free, appropriate public education provided at public expense. ▶ An Individualized education program (IEP) must be created. ▶ An IEP must specify the child's unique educational needs, levels of performance, measurable annual goals and objectives, and services that will be provided to help the child attain those goals.
Least Restrictive	▶ Students with disabilities must be educated with children without

Environment (LRE)	disabilities to the maximum extent appropriate including with aide, assistance or other services. ▶ The IEP must contain a justification when the nature or severity of a child’s disabilities is such that they cannot receive an appropriate education, participate in extracurricular activities, or receives services such as transportation with nondisabled peers.
Due Process Safeguards	▶ Consent from a child’s guardian(s) must be obtained for all subsequent evaluations and placement decisions regarding special education. ▶ Schools must maintain confidentiality for students, preserve records and make records available for guardians on request. ▶ Guardians may obtain an independent evaluation at public expense if there is disagreement in the evaluation. ▶ When there is disagreement on the identification, evaluation, placement, or provision of a free, appropriate public education for the child, the guardians may request mediation or a “due process” hearing.
Parent and Student Participation and Shared	The design and implementation of special education services must be

Decision Making	done in a collaborative manner with the student and their guardians.

An element of IDEA involves the right to a public education “within the least restrictive environment.” This idea of least restrictive environment means that the child will be placed in the same settings as typically developing children insomuch as their disability will allow them to meet IEP goals in that setting. Full “inclusion” conceptualizes *all* education provided alongside typically developing children as every child’s right, while proponents of “least restrictive environment” posit that the environment is determined by the child’s individual educational needs.

Special educators have long advocated “non-categorical” approaches to children with ID. Such approaches do not consider the cause of the child’s disability, and even knowing about the etiology of the disability has been considered harmful, possibly leading to increased stigmatization. However, advocates for “etiology-based” educational interventions suggest that the cause of the child’s ID can influence behavior, and relative strengths (or weaknesses) in language versus other abilities and across cognitive domains. Indeed, some syndrome-specific organizations (e.g., DS, PWS, Williams syndrome) have published best practice guidelines for both medical and psychosocial interventions, though such guidelines for rarer syndromes are lacking.

For example, children with DS show difficulties in linguistic grammar, expressive language, and articulation, even as their abilities in visual short-term memory appear relatively strong. Children with Williams syndrome generally show higher language (verbal) than visuospatial abilities, while children with either Prader–Willi or FXS show stronger abilities in simultaneous (i.e., Gestalt) processing compared to sequential processing. In each instance, educators and test-constructors have devised specific, tailored educational approaches that play to the child’s strengths rather than focusing on improving weaknesses alone. Similar approaches might also be designed and prove effective for children with different ID syndromes. However, while “etiology-based” educational interventions hold promise, such approaches may not prove effective for every child with a particular syndrome and need to be considered in light of the individual child’s strengths and weaknesses.

Adult Services. Federally mandated school services serve students with disabilities from age 3 to age 21. There is a federal mandate requiring youth with disabilities age 16 and older to have a postsecondary transition plan written into their IEP. This plan typically includes teaching vocational and adaptive skills in support of long-term life goals. Students with ID, their parents, and the school team work together to determine the most appropriate long-term goals for each young adult.

If a student with an IEP does not graduate with a high school diploma, they are eligible for the school district’s “transition program.” Each district’s transition program is unique, but most contain some degree of work experience in the community. Once an individual with ID turns 21, service delivery comes under the auspices of each state’s department of developmental disabilities. In contrast to educational services, adult services are not federally mandated. States thus vary widely in their services and how they offer them. Services are often spread out across various locations, and eligibility and access to services can be difficult.

During the adult years, residential and vocational services predominate. Residential services run the gamut from institutional to community-based, and from constant to no supervision. More restrictive placements involve large or small institutional residences, which mainly serve the most severely impaired individuals. Group homes for four to eight residents are probably the most common residential option; these homes typically exist within residential neighborhoods and provide round-the-clock staff to ensure safety and consistent programming. Supervised living arrangements usually consist of apartments that are shared by a few persons with ID; these residents receive visits from program staff, who often instruct residents in cooking, cleaning, and shopping. Unsupervised apartments, where individuals live by themselves or with a roommate under little supervision, mainly succeed with clients who have milder intellectual impairments and fewer behavioral problems.

Vocational services also range from most to least restrictive. Most restrictive are sheltered workshops, in which individuals with ID assemble or test products, working next to others with disabilities. Supported employment involves a job coach or other specially trained individual to work with the client to find a job, to learn how to take public transportation to get to a job, and to acquire the technical and social skills needed to handle the job. These coaches often initially shadow the individual with ID at the workplace and provide support as needed. Competitive employment is the least restrictive job option for adults with ID and involves a job with the same pay levels and benefits that a nondisabled person would have, but also with the same pressures and responsibilities for work performance. As in unsupervised apartment living, competitive employment is an option for the least impacted individuals.

Supports

In addition to services provided by early intervention, schools, and adult service agencies, individuals with ID and their families can benefit from other supports, including short- or longer-term respite care (allowing families a break from full-time care), specialized summer camps, and programs such as Special Olympics. In addition, most states have specialty clinics for behavioral and medical management of certain types of ID, such as autism spectrum disorder.

A wide variety of organized groups are available for parents of children with disabilities and for specific types of disability. Sibling groups and networks are also available, and the federal government fosters service and advocacy through the University Affiliated Programs (UAP’s) in almost every state.

Legal Issues in Intellectual Disability

FORENSIC ISSUES FOR INDIVIDUALS WITH ID. There is some evidence to suggest that individuals with borderline IQ and mild ID are overrepresented within the criminal justice system. Individuals with more severe or profound ID may be "protected" by factors including supervision from caregivers and a reduced range of social activities and community interface. Persons with ID are also more likely to be the victims of crime and other forms of abuse and maltreatment.

Relevant Legislation. Early intervention and educational services became widespread following the passage of PL 94–142 (the Education for all Handicapped Children Act of 1975); this legislation was extended and modified by IDEA, the IDEA of 1990, with amendments in 1997 and 2004. Major provisions of IDEA are outlined in Table 39–11.

ID is considered one of 13 disabilities defined under IDEA (see Table 39–12). Section 504 of the ADA protects anyone with a "physical or mental impairment which substantially limits a major life activity," and who "has a record of such impairment," or is "perceived as having such impairment" from discrimination. Students who do not qualify for an IEP can still receive classroom accommodations under a "504 Plan" according to ADA.

The ADA of 1990 spells out four aims: (1) to provide a clear and comprehensive national mandate for the elimination of discrimination against individuals with disabilities; (2) to provide clear, strong, consistent, enforceable standards addressing discrimination against individuals with disabilities; (3) to ensure that the Federal Government plays a central role in enforcing the standards established in the Act on behalf of individuals with disabilities; (4) and to invoke the sweep of congressional authority, including the power to enforce the 14th Amendment and to regulate commerce, in order to address the major areas of discrimination faced day-to-day by people with disabilities. The ADA represents a major turning point in the assurance of the rights of persons with disabilities who, even 50 years ago, were frequently institutionalized and compulsorily sterilized in misguided efforts to protect society from this population. In contrast, the prevailing paradigms in developed countries are those of community integration and support. Disabilities law over the past three decades ensures that all children with disabilities receive a "free appropriate public education" in the "least restrictive environment," and that reasonable accommodation is made for the employment of adults. Clinicians working with this population have a personal obligation to provide an accommodating environment, and should familiarize themselves with local guardianship, informed consent, and abuse reporting laws to best serve this population.

Table 39–12.
Disabilities Defined by IDEA

Autism

Specific Learning Disorder

Oren Boxer, Ph.D.

Humans are not born to read, write, spell, or perform arithmetic calculations: These are skills that must be learned. In contrast to oral language skills, which humans have possessed for over 100,000 years, cultural symbols used to represent specific numbers and speech sounds were invented only a few thousand years ago. Reading was invented approximately 5,400 years ago; symbolic arithmetic is more recent since the Arabic notation was not available even a thousand years ago.

These arbitrary cultural symbols, which are the foundational codes for reading, writing, and arithmetic, are not acquired “naturally” by simple exposure; each human being has to learn these symbols as well as how they map onto specific speech sounds, specific quantities, and numerals. The process of developing these literacy and numeracy skills reorganizes and changes everyone’s brain. This is because the human brain did not evolve to accommodate the recent human invention of symbols, which are far too recent to have exerted any evolutionary pressure on brain evolution. Thus, during the human developmental period, existing functions and networks in the brain are “recycled” for the new uses. For example, learning to read involves the creation and automation of an efficient interface between vision and spoken language (“visual word form area” in the left visual cortex); learning arithmetic involves creating connections with nearby areas of the parietal cortex that code for space and eye movement.

Multiple skills are involved in learning to process one's cultural symbol systems. These include the awareness that spoken language can be segmented into smaller units (words, syllables, phonemes) and mapped onto written, visual symbols (e.g., letters, characters, numerals); the ability to rapidly identify letters, letter clusters, and words (orthographic awareness); the ability to extract meaning from this written language; and the ability to transcode meaning between symbol systems (e.g., to understand that the symbol "3," the quantity of three dots (***), the spoken word "three" (/th/ /r/ /ee/) and the written word "three"; all represent "threeness" (see Table 40–1 for definitions of key terms related to reading and number sense).

For a subgroup of children, at least 6%, the multidimensional developmental task of learning to process and use cultural symbols present major lifelong challenges that are unexpected, given their abilities in other developmental domains. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) uses the term "Specific Learning Disorder" (SLD) to describe persistent and impairing problems in acquiring and using the cultural symbols that are required for reading, writing, and arithmetic.

Table 40–1.

Definition of Key Terms Used in Relation to Specific Learning Disorder

Term	Definition
Alphabetic principle	The insight that words are made up of sounds and each sound can be signified by a symbol.
Phoneme	Smallest sound units in a word: The smallest unit of speech that distinguishes one word from another (e.g., the word “peach” has three phonemes: /p/ /ea/ /ch/; the phoneme /p/ distinguishes the word “peach” from “teach”).
Phonemic awareness	An explicit awareness that there are discrete speech sounds (phonemes) in speech. It begins to emerge between ages of 2 and 4 years, takes several years to develop, and is crucial to success in reading and spelling. For example, the child must be able to isolate the phoneme /p/ in words such as “pet,” “peach,” and “pear” to fully understand that the grapheme “p” represents this sound and to associate the sound with this letter when attempting to decode a word like “port.”
Phonologic awareness	An explicit awareness that spoken language comprises discrete units, ranging from words and syllables to smaller subsyllabic units of onsets and rimes, and phonemes. It includes phonemic awareness.
Phonologic coding	Translating the letters or spelling patterns of a written word into speech patterns to identify the word and gain access to its meaning.

Phonics	An instructional approach for teaching children the systematic relationship between letters and sounds and how to use that system (alphabetic principle) to read words. In other words, instruction in phonics requires the child to have some level of phonemic awareness.
Onset-rime	Parts of monosyllabic words in spoken language: These units are smaller than syllables but larger than phonemes. An “onset” is the initial consonant sound of a syllable (the onset of “peach” is “p-”). The rime is the part of the syllable that contains the vowel and all that follows it (the rime of “peach” is “-each”).
Orthography	The representation of the sounds of a language by written or printed symbols. Patterns link graphemes (letter) to sounds (phonemes). Orthography describes or defines the set of symbols (e.g., graphemes, diacritics) used and the rules about how to write these symbols.
Orthographic transparency	Deep orthographies are writing systems (such as English) that do not have a one-to-one correspondence between the spoken phoneme and the written grapheme. A “shallow” orthography means that the correspondences between letters and sounds (graphemes/phonemes) in the writing system are close to one-to-one (e.g., Finnish, German).

SIGNIFICANCE OF SLD FOR PSYCHIATRISTS

SLD has high comorbidity rates with other common psychiatric disorders, ranging from attention-deficit/hyperactivity disorder (ADHD) (most common), anxiety, and mood disorders, and suicide, to substance abuse (least common). Thus, clinicians need to consider the presence of SLD when assessing for these other psychiatric disorders. Also, the burgeoning concern about health literacy and health numeracy in the medical literature highlights the need for clinicians to understand the medical implications of SLD. Health literacy is defined as the ability to obtain, process, and understand basic health information and services needed to make appropriate health decisions; health numeracy is defined as the individual-level skills needed to understand and effectively use quantitative health information (e.g., dose, quantity, probability) to guide health behavior and decision making. Basic reading skills (e.g., letter–sound knowledge and word recognition), reading comprehension, and basic numeracy skills are core attributes that underlie health literacy and numeracy. Poor health literacy and numeracy are independent predictors of health disparities, worse health outcomes, and mortality.

Recent surveys of the readability of patient education materials and medical research consent forms typically indicate that many of these materials have higher-than-acceptable levels of readability for the public. For example, the American Academy of Pediatrics reported that at least half of their materials manifest unacceptably high readability levels. Few studies have investigated the readability of patient education materials in psychiatry, which is of particular concern, given the low educational attainment of many patients with mental health illnesses. Low numeracy skills constrain patient choice, reduce medication compliance, impair risk communication, and affect medical outcomes. SLD tends to run in families, so patients and their families may have great difficulty accessing patient education materials and comprehending dosage instructions or nonpharmacologic interventions. Clinicians in the workplace may also have SLD themselves (e.g., almost 2% of medical students declare a diagnosis of SLD in reading upon entry to medical school), which may pose additional challenges in the effective performance of their clinical duties. Thus, an understanding of SLD and knowledge of effective strategies to enhance the clinical performance of clinical trainees and certified clinicians with SLD is of key importance for clinical educators.

To understand SLD, it is necessary to understand how the neuroplasticity of the human brain makes it possible to learn to read, write, and calculate, how the acquisition of literacy and numeracy transforms the brain, and how disturbances in brain development disrupt the normal acquisition of reading, writing, and arithmetic. Two of the most engaging accounts of the history and neuroscience are Maryanne Wolf's Proust *and the Squid* written in *2007,* and Stanislas Dehaene's *Reading in the Brain*, published in 2009. Two additional accounts of the earliest invention of numerals and how the human brain learns to understand and manipulate numbers, are Stanislas Dehaene's book, *The Number Sense*: *How the Mind Creates Mathematics,* written in 2011, and *Finding Zero*, by Amir Acxel, a mathematician's personal account of his journey to find the first "zero"—the keystone of our current number system, which he located on an inscribed stone in an old shed in Cambodia.

DEFINITION

SLD differs from most other mental disorders recognized by DSM-5, in that not only is it a clinical condition recognized and defined in the medical field, but also it is a discrete category of special educational needs (a.k.a., "exceptionalities") recognized and defined in the field of education. One major challenge for clinicians, educators, parents, and researchers alike, is that the purpose of classification differs in the medical/mental health and educational systems, as do their underlying concepts and definitions of SLD. Thus, clinicians who diagnose SLD must understand both the medical and educational definitions, as well as their different implications for accessing school-based supports and intervention services.

Medical/Psychiatric Definition

According to DSM-5, SLD is a Neurodevelopmental Disorder that involves marked and persistent difficulties in learning and using one’s cultural symbol systems (e.g., alphabetic letters, characters, Arabic numerals) that are required for skilled reading, writing, and arithmetic. SLD disrupts the normal pattern of learning these essential academic skills and is not simply a consequence of an intellectual disability, sensory deficits, other mental or neurologic disorders, lack of opportunity of learning or proficiency in the language of instruction, or inadequate educational instruction. Difficulties learning keystone (foundational) academic skills of reading, writing, and arithmetic may also impede learning in other academic subjects (i.e., history, geography, science) but those problems are attributable to difficulties learning the basic underlying academic skills.

Neurodevelopmental disorders are complex and heterogeneous conditions arising from perturbations of the central nervous system, typically during the pre- and perinatal period, which interfere with the development of language and speech, motor skills, attention, behavior, memory, learning, or other neurologic functions. Neurodevelopmental disorders are typically heritable, show early onset, persist through the lifespan, and impair academic, social, occupational, and mental health outcomes. DSM-5 delineates six neurodevelopmental disorders, many of which often co-occur: Intellectual Disabilities, Communication Disorder, Autism Spectrum Disorder, ADHD, SLD, and Motor Disorders. The neurodevelopmental disorder of learning (i.e., SLD) represents the extreme bottom end of normal distributions of culturally acquired skills, rather than a discrete categorical entity.

Like other neurodevelopmental disorders, SLD is understood to be a heterogeneous condition, in which the learning difficulties may be either selective (e.g., occur only with learning one specific aspect of reading such as word decoding) or broad (e.g., occur in learning to decode words, spell, understand what one has just read, as well as in arithmetic calculation), and frequently coexists with other neurodevelopmental (e.g., with Communication Disorders, ADHD) or psychiatric traits or disorders (e.g., with anxiety, anxiety disorders).

Moreover, SLD is understood to be a heritable, chronic condition of childhood that typically persists into adulthood, albeit with changes in the ways the learning difficulties manifest.

Medical practitioners must understand that a medical diagnosis of SLD, using the DSM or ICD classification systems, does not necessarily mandate eligibility for special assistance at school.

Federal/Educational Definition

In the field of education, the term “Learning Disabilities” is used to delineate a specific category of “special learning needs,” that mandates the provision of special education and other services to permit more equitable access to the curriculum and promote their learning.

In the United States, the conceptualization and definition of “Learning Disabilities” has been strongly influenced by the federal definition adopted by the U.S. Office of Education in 1969, operationalized by the U.S. Office of Education initially in 1977 (Individuals with Disabilities Education Act [IDEA]), and reauthorized in 2006 to determine eligibility for special education services that must be provided by all public schools. The 1977 IDEA definition of a specific learning disability refers to:

> A disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, which may manifest itself in an imperfect ability to listen, think, speak, read, write, spell, or do mathematical calculations. The term includes such conditions as perceptual handicaps, brain injury, minimal brain dysfunction, dyslexia, and developmental dysphasia.

Note that the federal definition of Learning Disabilities includes oral or spoken language impairments, which are classified as Communication Disorders in psychiatric taxonomies and differentiated from SLD. Moreover, the educational definition incorporates notions of presumed etiology (i.e., deficits in underlying psychological processes), whereas psychiatric classification does not.

Identification of specific learning needs in the educational system mandates eligibility for special education services. Due in part to differences in the purpose of identification, the educational system may identify some children as having special educational needs who would not meet the clinical threshold for a diagnosis of SLD in the medical system. The reverse is also true in that some students meet the diagnostic criteria for an SLD in the medical system but are not identified as requiring special education in their school and therefore are not SLD eligible. Children with higher intellectual development are especially at risk for this scenario because they can often access the curriculum and perform at grade level despite underlying cognitive weaknesses which significantly undermine the efficiency of their learning. For example, an intellectually gifted student (typically defined as having an IQ standard score of 130 or greater) would need to perform below grade level (academic achievement near a standard score of 78) to be eligible for special education services. This student would need to perform over three standard deviations lower in one or more academic domains. A student with an average IQ (standard score of 100) would only need to perform 1.5 standard deviations lower to be identified as having special education needs.

One substantive problem with the educational definition is that standards of identification of SLD differ across school boards, postsecondary institutions, and across countries, so that an individual identified as SLD by one school board, or in one region of the country, or in one country, may not be identified in another. Moreover, as both educational laws and psychiatric taxonomies change over time, different groups of individuals are identified as having SLD or Learning Disabilities, depending on the specific set of criteria applied. Thus, the terms Specific Learning Disorder and Learning Disabilities are not synonymous. To date, there is no consensus definition of this condition: Current assessment and diagnostic practices in both medical and educational systems are varied, often opaque and discriminatory, and therefore vulnerable to legal challenges.

HISTORY AND COMPARATIVE NOSOLOGY

History

The term “Learning Disability”, credited to Samuel Kirk in 1962, was first recognized as a formal category in the field of special education in the 1960s, although the first clinical case of a child’s unexplained difficulties learning to read had been described much earlier in the United Kingdom in 1896. In 1963, parents, educators, and policy specialists in the United States, agreed on the term “Learning Disabilities” to refer to a large group of individuals who had unexpected and significant difficulty learning to read, write, or do arithmetic, despite average or above intellectual ability.

Kirk defined learning disability in 1962 as:

> a retardation, disorder, or delayed development in one or more of the processes of speech, language, reading, spelling, writing, or arithmetic resulting from a possible cerebral dysfunction and/or emotional or behavioral disturbances and not from mental retardation, sensory deprivation, or cultural and instructional factors. (Kirk SA. *Educating Exceptional Children.* Houghton Mifflin; 1962:263.)

Early terminology, which focused primarily on difficulties learning to read, included terms such as reading blindness, word blindness, congenital word blindness, strephosymbolia, specific reading disability, specific developmental disability, unexpected reading failure, specific reading retardation, and garden-variety poor readers, and “dyslexia” (from the Greek *dys* and Latin *lexia*). Descriptions of difficulties learning arithmetic emerged later. For instance, Gerstmann, in 1957, described an “isolated disability to perform simple or complex arithmetical operations and an impairment of orientation in the sequence of numbers and their fractions” (Gerstmann syndrome). The term “dyscalculia” (from the Greek *dys* and Latin *calculia*) was used by Cohn in 1968, to refer to a “failure to recognize numbers or manipulate them in an advanced culture,” and later by Kosc as “a disorder of the special abilities for mathematics without a simultaneous defect in general mental abilities.” The first descriptions of *developmental* disorders of written language in the 1960s were based on case studies of isolated impairments of written expression, with other forms of verbal behavior remaining intact. Since these early descriptions involved visual–motor integration, the term *dysgraphia* (literally “difficulty with writing”) was the first diagnostic label associated with disorders of written expression. Although it is sometimes used as a synonym for the disorder of written expression, the term *dysgraphia* is used more correctly to describe difficulties with the mechanics of handwriting. By contrast, SLD in written expression emphasizes difficulties with accurate and fluent generation and composition of written text.

Terminology and conceptualizations of SLD differ widely among professionals from different disciplines or different countries; they also differ between professionals and the lay public. For instance, in the field of research, the term “dyslexia” is typically understood to refer primarily to problems in decoding single words and is associated with phonologic deficits, but lay understanding differs and is broader (e.g., often incorporates concepts such as sensory, perceptual, motor, and emotional difficulties). Also, in Europe, the term “dyscalculia” is used to refer to developmental problems in basic numerical processing, such as automatic or implicit processing of quantities or numbers. By contrast, the term is used rarely in North America, which instead uses terms such as “mathematical disabilities” or “arithmetic difficulties” that implicate a broad array of problems with arithmetic facts, arithmetical procedures, and mathematical reasoning.

Nonetheless, early perspectives of Learning Disabilities shared some commonalities: (a) recognition that impaired academic skills (reading, arithmetic) occur in the context of average or even superior intellectual abilities; and (b) a focus on impairments in specific component skills (e.g., word reading, calculation) rather than viewing an academic domain as a unitary construct. Other important insights were that these disabilities were believed to be congenital, heritable, and manifest more commonly in males than females. However, whether learning disabilities could occur either as an isolated domain-specific deficit or be accompanied by deficits in other academic domains remained controversial, as it does today.

The advent of IQ tests in the early 1900s such as the Stanford-Binet, permitted direct evaluation of the observed difference in a person’s academic skills and intellectual ability. In 1920, the neurologist Samuel Orton postulated a neurologic basis for developmental reading difficulties, suggesting that delayed development of specialization of the left hemisphere for language was potentially causal. However, it was not until the 1970s that an adequate knowledge base was established, which localized the difficulties at the single-word level and pinpointed the cause in most cases as language-based deficits in phonologic processing. The 1940s, known as the era of the “brain-damaged child,” incorporated a broader array of cognitive deficits into the category of Learning Disabilities, including perceptual, perceptual–motor, and attention difficulties. However, it was not until the 1960s that Learning Disabilities emerged as a formal category and the notion of a discrepancy between IQ and achievement prevailed as one of its defining features. The concept was broadened to include perceptual as well as linguistic processing deficits as underlying learning disabilities.

As previously mentioned, in the 1970s in the United States, the conceptualization of Learning Disabilities was consolidated in the federal definition (U.S. Office of Education, 1977) and in the definitions of professional organizations (e.g., National Joint Committee on Learning Disabilities, 1978), and achieved official federal status as an eligible category for direct services (Public Law 94–192). The notion of underlying deficits in cognitive processing as causal factors was instantiated in the conceptualization of Learning Disabilities and the condition included conditions such as perceptual disabilities, brain injury, minimal brain dysfunction, dyslexia, and developmental dysphasia (thereby continuing its earlier conceptualizations), but excluded learning problems resulting from visual, hearing, or motor disabilities, mental retardation, emotional disturbance, or environmental, cultural, or economic disadvantage. Thus, this prevailing legal definition restricts the concept of Learning Disabilities to a language-based disorder and does not include nonlanguage-based learning difficulties, such as dyscalculia, as defined by some researchers. In other words, speech and oral language problems are included in the federal category but are coded separately as Communication Disorders in psychiatric (ICD, DSM) taxonomies. Thus, the federal/legal and medical categories of Learning Disabilities differ in the range of learning difficulties they encompass as well as in the imputed boundaries between disabilities/disorders.

Comparative Nosology

The first psychiatric/medical descriptions of SLD in reading or mathematics occurred in DSM-III (1980), with SLD in written expression added in DSM-III-R (1987), under the general category of “Academic Skills Disorder” on axis II. These learning difficulties were classified into three separate disorders: *developmental reading disorder, developmental arithmetic disorder,* and *developmental expressive writing disorder,* respectively. By contrast, DSM-IV-TR–coded learning disorders on axis I, as does DSM-5. Both of these DSM versions dropped the “developmental” descriptor that is used by other clinicians and researchers to distinguish between developmental versus acquired learning problems (e.g., as a result of traumatic brain injury, dementia, stroke). There was no compelling logic for the coding shift from axis II to axis I, but the shift may have served to render these impairing learning disorders more salient for diagnosticians, whose clinical practice focuses primarily on other types of mental health problems. The 2013 revision of DSM (DSM-5) no longer recognizes subtypes of SLD distinguished in previous DSM versions. Instead, it recognizes an umbrella category of SLD and then uses specifiers for clinicians to use to detail more precisely the range of academic skills that are impaired *at the time of assessment*, thereby recognizing the possibility of changes in the manifestation of SLD with development or educational instruction. Specifiers refer to three major academic domains that may be affected (i.e., reading, writing, mathematics) as well as the type of skills impaired. For instance, *SLD in reading* may manifest as difficulties in accurately decoding single words (a.k.a., dyslexia), fluency in reading text accurately, or reading comprehension; *SLD in written expression* may manifest as impairments in spelling words accurately, inaccurate use of grammar and punctuation, or in the clarity or organization of written expression; *SLD in mathematics* may manifest as impairments in basic number sense, memorization or retrieval of arithmetic facts, accurate or fluent calculation, or accurate math reasoning.

The DSM-5 conceptualization of “SLD in reading,” “SLD in written expression,” and “SLD in mathematics”—although comparable with—is not identical to other terms used primarily in the fields of education and in educational and clinical psychology (e.g., “reading disabilities,” “developmental dyslexia,” “dyslexia,” “developmental expressive writing disorder,” “written language disabilities,” “dysgraphia,” “spelling disorder,” “math disabilities,” “specific disorder of arithmetic skills,” “dyscalculia”).

The DSM-5 nosology of SLD also differs from that of ICD-10, which differentiates even more specific subtypes of SLD than does any version of the DSM. For instance, although ICD-10 distinguishes three subtypes that appear to be like those of DSM-IV-TR (“specific reading disorder,” “specific spelling disorder,” “specific disorder of arithmetic disorder,” as well as “mixed disorder of scholastic skills”), they differ in their requirement for the restriction of impairment to that specific academic domain. For instance, the categorical subtype of Specific Reading Disorder excludes individuals who also manifest impairments in arithmetic; Specific Spelling Disorder excludes those who also manifest a reading disorder; individuals who manifest impairments in more than one academic domain are given the diagnosis of Mixed Disorder of Scholastic Skills.

Ongoing concerns about the DSM (and ICD) approach to nosology have spurred a recent initiative by the U.S. National Institute of Mental Health (NIMH) to focus on alterations in the brain and its substrates that might signal the location and source of human mental stresses or woes, specifically the RDoC (Research Domain Criteria Project were created by Cuthbert and Insel). The RDoC framework is a research strategy with a dynamic matrix of elements at its core that includes six major domains of human functioning (social processing, negative valence systems, positive valence systems, arousal and regulatory systems, and cognitive systems). Within each domain are behavioral elements that range from normal to abnormal with the understanding that behaviors are affected by environmental and neurodevelopmental variables.

EPIDEMIOLOGY

SLD is one of the most frequently diagnosed Neurodevelopmental Disorder. A recent epidemiologic study suggested that the lifetime prevalence of SLD is around 10%, with the prevalence being greatest among children with special health care needs (28%) compared to typically developing children (5.4%). However, prevalence rates vary as a function of the definition, cut-offs, and instrumentation used. Moreover, most estimates are based on the prevalence of a single manifestation of SLD (e.g., in reading or mathematics) without considering the co-occurrence of SLD across academic domains. Nonetheless, SLD in the domain of reading (particularly at the word level) is the most common and well-studied manifestation, affecting at least 90% of all individuals identified as having SLD. It is estimated that two of five children in special education have been placed because of reading difficulties. However, children showing a deficit in one academic domain (e.g., reading) are highly likely to show deficits in other domains as well (e.g., spelling, written expression, mathematics), either concurrently or emerging later, as demands for efficient and fluent use of basic academic skills increase.

To date, there are a handful of studies of prevalence of SLD based on DSM-5 criteria. The most recent one attempted to understand the prevalence of SLD, as well as comorbid disorders, and risk factors in elementary school children in Turkey (Senol et al., 2020). The study found that the prevalence rate of SLD was 6.6%, impairment in reading was 4%, in mathematics was 3.6%, and in written expression was 1.8%. Nearly 63% of the children with SLD had one or more comorbid diagnoses, with ADHD being the most common (54.9%). Sex differences were observed as well with a higher prevalence of SLD among males. Another study conducted in a German school population found that SLD across several academic domains (and subdomains, such as word reading, fluency, and comprehension) occurred as frequently as an isolated disorder in any one domain. The rates of multiple-domain SLD were high (particularly for co-occurrence of arithmetic and spelling difficulties) even when applying the stricter criteria of achievement scores of 1.25 to 1.5 standard deviations below the mean for age. No sex differences were observed when considering SLD across multiple academic domains, however, more girls manifest problems in arithmetic and more boys had spelling problems and combined reading and spelling problems compared to girls. A third study, conducted in Brazil, a low- to middle-income country, reported that almost 8% of the representative sample (about 1,600 second- to sixth-grade children from 4 geographic areas) manifest SLD across the academic domains (global impairment), 7.5% in reading, 6% in arithmetic, and about 5% in written expression. Moreover, SLD with global impairment was significantly associated with ADHD; SLD in arithmetic was associated with both ADHD and Anxiety Disorders.

Although more cross-cultural epidemiologic studies of the prevalence of SLD based on full DSM-5 criteria are needed, the practical implications of the existing studies are that assessment for SLD should include all three academic domains as well as the subskills. Clinicians are advised to specify the diagnosis of SLD by providing additional information about the learning domains that are affected at the time of assessment (i.e., implementing Specifiers for SLD listed in DSM-5, as described in the later subsection on diagnosis).

ETIOLOGY

Different levels of explanation must be considered in understanding causal influences on learning academic skills. Converging evidence from cognitive, neuroimaging, twin, family, behavioral, and molecular genetic studies indicates that SLD is a multifactorial neurodevelopmental disorder arising from the complex interplay of biologic and environmental risk factors that shape the development of brain systems underlying academic learning. Reflecting the multiple constellations of variables that shape development and contribute to learning disorders, research in SLD has shifted from a single-deficit model to a more dynamic multiple deficit model (MDM; Pennington 2006). This model proposes that the etiology of behavioral disorders is multifactorial and influenced by multiple risk and protective factors which can be environmental or genetic. The interaction of risk and protective factors alter the development of neural systems that mediate cognitive functions and ultimately produce behavioral symptoms that are identified in the assessment of learning disorders. Over the past 15 years since this model was introduced, it has helped to identify comorbidity between learning disorders and neurodevelopmental disorders (e.g., ADHD), and has also aligned with NIMH RDoC in efforts to identify transdiagnostic risk factors in psychiatric disorders (Insel et al., 2010).

The use of cognitive multiple deficit models in dyslexia and dyscalculia have also proven successful. A recent study, Peterson et al., in 2017, aimed to employ a cognitive multiple deficit model to identify cognitive predictors unique to specific skill domains (word reading, math ability). The study found that a single common cognitive predictor, verbal–conceptual skills, contributed to the overlap between reading and math. It also found that processing speed contributed to the overlap between math and attention. Results of the overall study revealed that cognitive factors accounted for a large majority of the variance in reading and math ability (approximately 80% to 90%).

Like any predictive model, the MDM has some problems. First is that despite the overall theme that multiple deficits ultimately contribute to an SLD, research in dyslexia using the MDM have found that some children (approximately 25%) can be explained by single deficits. Because much of the work using MDM has been cross-sectional it is unclear if the association between cognitive deficits and behavioral symptoms are causal, consequence, bidirectional, or related to other variables. Despite these limitations, it appears that the MDM has great potential to not only help map the etiology of SLD, but also highlight related and effective treatment. There is some evidence that individual cognitive factors are helpful in treatment planning. For example, optimal reading instruction may vary as a function of cognitive characteristics such as vocabulary development. This suggests that further development of the MDM can result in a more detailed understanding of neurodevelopmental disorders and thus a more tailored treatment approach.

Despite growing utility of the MDM in understanding the etiology of SLD, the notion of a single deficit model remains and continues to present in SLD literature and in clinical care. For example, in contrast to the growing evidence that dyslexia can present without a phonologic deficit, some in the assessment and clinical community assert the necessity of a phonologic deficit in the disorder.

Emerging evidence supports the likelihood that multiple and interacting genetic factors, brain differences, cognitive deficits, and environmental stressors underlie SLD, each contributing to the overall outcome.

Genetic Factors

Behavioral Genetics. Family and twin studies indicate that most dimensions of cognition (general intelligence, learning to read, spell, do arithmetic) are moderately heritable: About 50% of variance in a population is attributable to genetic influences, with increased importance with increasing age. For example, heritability estimates of individual differences in reading skills increase from about 20% of variance at age 6 to about 80% at age 12. Increases in heritability estimates with age most likely reflect a reduction of environmental influences once children enter formal education and increasing correlations between genotype and environment as with increasing maturity and independence, individuals tend to select environments that fit their abilities (genotype). A recent meta-analysis, based on 5,330 monozygotic and 7,084 dizygotic twin pairs in unselected samples (i.e., typically developing), estimated heritability of academic achievement at 73% for reading words, 44% for spelling, 49% for reading comprehension, 57% for mathematics, and 645 for language. Moreover, a common genetic factor has been demonstrated among spelling, reading fluency, and reading comprehension, with genetic influences accounting for around 80%

of the covariation between core academic skills, such as reading, spelling, and arithmetic, with many of the same genes affecting the learning of various academic subjects independent of intelligence.

Twin studies involving large samples with diverse abilities (e.g., including typical readers and those with dyslexia) reveal common genetic influences across the range of ability and disability, suggesting that a particular set of genes affects academic learning in both typically developing samples and those with SLD. Also, despite the paucity of behavioral genetic research on SLD in mathematics, family studies indicate that the familial prevalence of dyscalculia is about 10-times higher than expected by chance and that genetic factors contribute to the observed covariance between reading and mathematics deficits.

It is important to note that not all individuals with SLD inherited the condition since twin studies also reveal that both common and unique environmental influences play a role, as discussed below. However, from a clinical perspective, the high heritability estimates for SLD highlight the importance of probing family history in the assessment for SLD and ensuring that parents and patients with SLD can read and comprehend any written reports or information brochures provided to them.

Molecular Genetics. To date, most molecular genetic studies have focused on genes implicated in reading ability and disability, particularly those associated with word reading and spelling difficulties, also known as dyslexia. Several candidate genes have been implicated (e.g., *DYX1C1*, *DCDC2*, *ROBO1*, *KIAA0319*, and the *MRPL19*/*C2ORF3* locus), with some being replicated in many studies. One problem is that most of the candidate risk SNPs identified so far for dyslexia have been in noncoding regions of the genome which are not well understood. Recent studies report genetic interactions between two *DCDC2* risk haplotypes (*READ1* alleles) and the risk haplotype *KIAA0319*, which influence both reading and oral language, as well as intelligence, with both protective and deleterious alleles. Findings from these studies are consistent with the generalist genes hypothesis and underscore the close association between Communication Disorders and SLD, which are conceptualized distinct disorders in DSM and ICD systems.

Molecular genetic studies of SLD in mathematics are sparse and findings inconsistent. For example, two genome-wide association studies failed to identify any significant associations and a third reported a significant genetic component underlying mathematical abilities but did not identify specific risk factors. Another genome-wide association study identified one marker (myosin-18B), that was not only associated with mathematical ability in two independent cohorts selected for dyslexia, but also was associated with brain alterations (reduced depth of right intraparietal sulcus that has been linked with numerical processing) in adults with low mathematical performance. However, this association was not replicated by another group of researchers using independent samples.

Neurologic Substrate

SLD in Reading. Most research has focused on dyslexia. Structural and functional neuroimaging studies have revealed brain regions that are most consistently involved in reading words and which are altered in dyslexia. These regions include inferior frontal, superior and middle temporal, and temporoparietal regions. Experienced readers also involve an area of the left fusiform gyrus, known as the *visual word form area*, which is activated for orthographic (print) processing. This reading network typically develops with age as children gain automaticity in specific skills required for reading.

Meta-analytic studies have revealed patterns of structural and functional differences in children, adolescents, and adults with SLD in reading words (dyslexia). The most common difference is reduced activation in *left* temporal, parietal, and fusiform (visual word form area) regions.

Given the abnormal development of white matter across posterior and anterior language networks related to phonologic skills, it has been proposed that dyslexia results from a white matter disconnection syndrome. This may also explain other deficits seen in dyslexia which rely on a strong connection between posterior auditory processing areas and anterior motor planning areas.

Family risk studies of dyslexia which are designed to compare children at high risk for dyslexia (significant family history of the disorder), without a family history of the disorder have helped to identify developmental precursors. Precursors are often cognitive or neural differences found in children from infancy to preschool who have not yet been exposed to formal reading instruction. Because many of these studies are longitudinal, these children have been followed over time. Once they have been diagnosed with dyslexia the researchers are able to review historical data related to neural and cognitive development and identify what discriminated them from children who were not diagnosed with dyslexia. These neural and cognitive differences were seen before the children were exposed to formal reading instruction, thus identified differences in dyslexia are not simply the result of poor reading development.

Other family risk studies following prereading children at high risk for dyslexia have revealed altered neurophysiologic responses to auditory stimuli (e.g., mismatched negativity) that show potential as an early endophenotype of dyslexia. Some of these biomarkers enhance or even outperform behavioral measures in predicting long-term reading outcomes: But, at present, none of these biomarkers can be used clinically to rule in or rule out the diagnosis of SLD in reading.

SLD in Mathematics. Evidence for the neurologic base of mathematical cognition and SLD in mathematics is sparse in comparison to that for reading and SLD in reading. However, converging evidence from structural and functional imaging studies indicate the *right* intraparietal sulcus as a major (but not sole) locus of brain differences and cognitive deficits in children and adults with SLD in mathematics. Alterations in other interconnected brain regions have also been observed, including posterior regions (bilateral intraparietal sulcus and fusiform gyrus) and prefrontal cortex (premotor cortex and middle frontal gyrus). Also, network analysis reveals multiple dysfunctional white matter circuits, suggesting a neurodevelopmental disconnection condition.

SLD Writing. fMRI studies of written language and spelling provide little evidence of a neurologic underpinning. Many of these studies have small sample sizes and are not exclusive to children. Only a handful of anatomical studies have isolated SLD in writing. Overall, many of the identified brain areas that relate to writing include frontal and parietal regions, as well as coordinated activation with the cerebellum. There does not seem to be a consensus of a neural network that is specific to written language, and many of the studies suggest a considerable overlap with networks related to linguistic processing and motor planning.

Cognitive Factors

The generalist genes hypothesis in learning disorders hypothesizes that shared genetic factors lead to shared cognitive difficulties across the various types of SLD. One domain-general cognitive deficit is executive functioning, which includes the control and coordination of short-term, working- and longer-term memory systems, encoding and retrieval systems, attention, and planning. Working memory, which refers to the ability to temporarily hold and manipulate auditory–verbal and visual–spatial information, while learning new information or problem solving, is believed to be impaired in most individuals with SLD. Thus, individuals with SLD have difficulties suppressing irrelevant information from working memory, as well as simultaneously holding and processing information, which manifests as difficulties updating what they know or have just learned. In other words, the more restricted working memory capacity associated with SLD makes it more difficult for these individuals to suppress irrelevant information and update new knowledge as they learn.

Working memory deficits will impair learning to read new words, which requires the ability to remember letter–sound combinations, their order, as well as the many special rules (e.g., “silent” letters, such as “g” in gnash or height, “e” at the end that changes the vowel sound but itself remains silent, as in “site”). Working memory deficits have an even greater impact on reading comprehension and writing: Reading comprehension requires updating information in working memory to monitor the meaning of each sentence and each paragraph, extract the main ideas, and construct mental images of the emerging situations and events; writing requires the ability to plan, organize, compose, and edit, while keeping in mind the writing goals, content, audience, as well as spelling, vocabulary, and grammar. Poor working memory will also impair mathematical abilities, including the ability to retrieve and hold math facts for use in computation, follow arithmetic procedures in calculation, and in math reasoning. A recent meta-analysis indicates the domain-general nature of working memory deficits across the various manifestations and severity of SLD, but with some indication of more severe verbal working memory deficits in individuals with SLD in reading and more severe deficits in visual–spatial working memory in those with SLD in mathematics.

Slow processing speed is another domain-general factor that has a negative impact on learning. For instance, rapid automatized naming, which refers to the ability to rapidly name familiar alphanumeric (letters, numbers) and nonalphanumeric (colors, objects) stimuli, is impaired in a substantial proportion of individuals with SLD. Although some research has shown distinct rapid naming profiles in students with SLD in reading versus SLD in mathematics (impairment in alphanumeric in the former and in nonalphanumeric stimuli in the latter), a recent meta-analysis concluded that rapid naming of nonalphanumeric stimuli is impaired in both manifestations of SLD, whereas alphanumeric naming may be more specific to SLD in reading. However, rapid naming deficits are not unique to SLD: They are also shared with other neurodevelopmental disorders (e.g., ADHD, Autism Spectrum Disorders, and Communication Disorders).

Language-based factors, although often linked in the older literature exclusively with SLD in reading (particularly its manifestation as “dyslexia”), are associated with all manifestations of SLD. For instance, oral language difficulties interfere with all aspects of reading, writing, and mathematics, although in the latter domain, the impact is primarily on those aspects of mathematics involving verbal processing. Impairment in a specific language-related skill, phonologic processing, is widely recognized as the core cognitive deficit in SLD in word reading. However, some evidence suggests that early phonologic deficits may have deleterious effects subsequently on learning arithmetic. For example, one study reported that over 50% of children with phonologically based reading difficulties but no apparent difficulties in learning basic arithmetic at age 5 years manifest learning difficulties in mathematics as well as continued problems in reading at age 7.

An ongoing controversy in the field of SLD is whether SLD in reading single words (dyslexia) is associated with a unique and potentially diagnostic set of cognitive deficits. However, the conclusions from a large-scale investigation of two population-based samples (U.S. cross-sectional study; international longitudinal study) are that cognitive predictors believed to play a causal role in dyslexia (e.g., phonologic processing, rapid automatized naming) are neither necessary nor sufficient for the diagnosis of SLD in reading. Moreover, the investigators concluded that the relationship between the cognitive measures and reading skill is probabilistic not deterministic or diagnostic. Also, it remains unclear whether cognitive factors are a cause, consequence, or correlate of SLD. Hence, DSM-5 does not include cognitive processing deficits in the diagnostic criteria for SLD.

Environmental Factors

Twin studies indicate that shared and nonshared environmental factors contribute up to about 40% or 50% of academic skill development, and to SLD, but the nature of these environmental factors is not well understood. Candidate risk factors include low socioeconomic status, the prenatal environment, and the postnatal learning environment provided by parents.

Prenatal Environment. Prenatal exposure to toxic substances, such as alcohol, tobacco smoke, lead, and other environmental toxins have been linked to neurodevelopmental outcomes. Prenatal exposure to tobacco smoke remains high despite the overall worldwide reduction in smoking among adults: A recent study reveals that 7.2% of women who gave birth in the United States smoked during pregnancy. Women between the ages of 20 to 24 had the highest rates of smoking at 10.7%. Known risks of maternal smoking and alcohol intake during pregnancy include premature birth, low birth weight, as well as fetal alcohol syndrome for prenatal alcohol exposure. However, findings for the outcomes in terms of subsequent academic achievement in the offspring are inconsistent, perhaps due to methodologic shortcomings of the studies in terms of exposure assessment, measurement of academic outcomes, and inadequate control or consideration of confounding factors. Nonetheless, a recent review of 30 studies concluded that both prenatal exposure to the ingredients in tobacco smoke and alcohol can result in a spectrum of adverse developmental outcomes, ranging in severity from intellectual disorders to more subtle negative impacts on academic achievement, memory, verbal abilities, and poor executive functioning.

More robust evidence comes from recent studies that postdate the above review. For example, a recent large-scale longitudinal study focusing specifically on reading outcomes of prenatal exposure to tobacco smoke found that high prenatal exposure to nicotine tobacco smoke (>17 mg nicotine per day) was negatively associated with reading performance, particularly in decoding single words and spelling, with greatest effects on children with poorest phonologic skills—suggesting a possible gene by environment effect. Another longitudinal epidemiologic study conducted in the United Kingdom examined the health and academic trajectories of children born in the late 1950s—an era in which there was a high rate of maternal smoking during pregnancy (about 30%)—from the prenatal period through to age 16. The research revealed that low birth weight, prenatal exposure to tobacco smoke, and poor school-aged health are negatively related to academic achievement in reading and math, suggesting a cumulative effect of early adversities. Also, a meta-analysis of the academic outcomes associated with children born very preterm (<32 weeks) or with very low birth weight (<1,500 g) reveals negative effects on IQ scores (by an average of 11 IQ points) and poor academic performance, with greater frequency of SLD in mathematics compared to SLD in reading. About two-thirds of children born very prematurely or with very low birth weight have special educational needs, especially for SLD in mathematics.

Family Environment. Parents of children with SLD may well have SLD themselves and so may be less able to engage in "code-focused" or "meaning-focused" activities with their children who have SLD: These activities refer to parent–child engagement in rhyming and counting games, teaching letter names and sounds, letter–sound pairs, teaching numbers and how to count (code-focused); and reading stories aloud in an interactive way or playing board games that involve symbol recognitions and counting (meaning-focused). However, although parents of children with SLD report being more stressed than parents of children without SLD, there is no evidence of poorer family functioning in families in which someone has SLD. Moreover, although the home literacy and numeracy environment, including parental SLD, predict children's growth in literacy and numeracy abilities in preschool and kindergarten years, by school age, genetic influences as well as basic skills knowledge (e.g., letter and number knowledge) tend to predominate.

Gene X Environment Interaction. The complex interplay between genetic and nongenetic influences has garnered relatively little empirical attention, given the general consensus that SLD arises from gene-by-environment interactions. However, some recent studies provide preliminary evidence for such interactions in SLD in single-word reading (a.k.a. dyslexia). For example, one study reports gene X environment effects between adverse prenatal factors (e.g., maternal smoking during pregnancy, low birth weight, socioeconomic status) and a genetic marker associated with dyslexia (*DYX1C1-1259C/G*) in 165 nuclear families in which at least one member had dyslexia. Findings revealed that the interaction of common “C” allele with lower birth weight was associated with lower reading scores, and the interaction between the rare “G” allele and maternal smoking during pregnancy was associated with poorer short-term and working memory scores.

Common Risk Factors, Signs, and Symptoms of Specific Learning Disorder

Preschool

- Lack of interest in playing games with language sounds (e.g., repetition, rhyming)
- Trouble learning nursery rhymes
- Problems counting correctly
- Frequent use of baby talk and mispronunciation of words
- Failure to recognize letters in own name
- Trouble remembering names of letters, numbers, or days of the week

Kindergarten

- Unable to recognize and write letters, write own name, or use invented spelling
- Trouble breaking down spoken words into syllables (e.g., “cowboy” into *cow* and *boy*)
- Trouble recognizing words that rhyme (e.g., “cat,” “bat,” “hat”)
- Trouble connecting letters with their sounds (e.g., letter “b” makes the sound /b/)
- Unable to recognize phonemes (e.g., does not know which of the set of words [“dog,” “man,” “car”] starts with same sound as “cat”)
- Unable to count in sequence beyond “4” (e.g., “1,2,3,4…um 7,11”)

Primary Grades (Grades 1–3)

- Receives reports of “not doing well in school”
- Continues to have problems recognizing and manipulating phonemes
- Unable to read common one-syllable words, such as “mat” or “top”
- Problems in connecting sounds and letters (e.g., “big” for “got”)
- Unable to recognize common irregularly spelled words (e.g., “said,” “two”)
- Difficulty in sequencing numbers and letters
- Complains that reading is hard and avoids or refuses to do it
- Difficulty learning simple math facts of 10
- Counting is often inaccurate above about 5 or 6 items

- Unable to identify the relevant numerical information or generate a math equation needed to solve a simple arithmetic word problem

Middle Grades (Grades 4–6)

- Mispronounces or skips parts of long, multisyllable words (e.g., says “conible” for “convertible” and “aminal” for “animal”)
- Confuses words that sound alike (e.g., “tornado” for “volcano”)
- Trouble remembering dates, names, telephone numbers
- Trouble reading small function words (e.g., “that,” “the,” “an,” “in”)

Middle Grades (Grades 4–6) *Continued*

- Gets the first part of a word correct, then guesses (e.g., reads “clover” as “clock”)
- Poor comprehension with or without slow, effortful, and inaccurate reading
- Trouble completing homework or tests on time
- Fear of (refuses) to read aloud, avoids reading
- Terrible spelling; unable to recognize correct spelling from plausible alternatives (e.g., necessary/necessery; friend/frend)
- Continues to rely on finger counting for simple arithmetic
- Difficulties mastering basic math facts (e.g., cannot remember that 3 + 2 = 5)
- Shows high levels of anxiety around any activity requiring basic arithmetic

High School, College, Work

- Slow, effortful reading of single words and connected text
- Trouble pronouncing multisyllable words
- Frequent need to reread material to understand or get the main point
- Trouble making inferences from written text
- Avoids activities that demand reading (reading for pleasure, reading instructions)
- Terrible spelling; the same word is misspelled in different ways within one piece of work
- Excessive problems generating written text: short, immature, not representative of the student’s knowledge or creative ideas

- Avoids writing activities; written expression is very short, immature, and disorganized
- Great difficulties in using arithmetic in functional activities (e.g., calculating tip percentage, calculating the amount of change required after a purchase, monitoring bank account)

General

- First-degree relative (parents, sibling) with current or history of SLD
- Slow learning to talk
- Anxious and embarrassed when asked to read or work out a problem in public (e.g., in class, workplace)
- Avoidance or refusal to read, write or do arithmetic
- Reluctance to go to school

The clinical implications of findings from current research on etiologic factors of SLD include the importance of including in an assessment for SLD the family history of SLD, the individual's prenatal and birth history, and for children with suspected SLD, an assay of their home literacy and numeracy environment. Clinicians are advised to be alert to the increased risk for SLD associated with prematurity, low birth weight, and prenatal exposure to tobacco smoke, alcohol, or other drugs.

CLINICAL FEATURES, ASSOCIATED PROBLEMS, AND DIAGNOSIS

Clinical Features

The learning difficulties manifest as an array of observable and persistent behaviors or symptoms that change across the lifespan, many of which are summarized in Table 40–2. These include (but are not restricted to) poor word recognition and difficulties sounding out words, frequently guessing words, reading slowly and hesitantly; difficulty understanding what is read (may get the basic facts, but not the deeper meaning); marked difficulties spelling words correctly;

poor sentence and paragraph structure in written work, with numerous punctuation and grammatical errors; difficulties understanding numbers and their relative magnitude and relationships; persistent use of primitive counting strategies (e.g., counting on fingers); difficulties recalling number facts and getting lost in the midst of arithmetic computation; and difficulties applying basic arithmetic concepts to solve quantitative problems.

These observable symptoms are not simply the consequence of an intellectual disorder, sensory deficits or neurologic disorders, lack of proficiency in the language of instruction, inadequate educational instruction, or lack of opportunity to engage in full-time formal schooling.

Signs and Symptoms of SLD in Reading. The most common and earliest manifestation of SLD in reading, particularly in the English language, is inaccurate, effortful, and slow reading at the word level (a.k.a., “dyslexia”). Recent evidence, however, has revealed that signs of SLD in reading can be detected even earlier. Differences in oral language development can accurately identify children who are at risk for dyslexia before they are exposed to formal reading instruction. In contrast to the common understanding that phonologic deficits are the strongest predictor of an SLD in reading, phonologic deficits are not a strong predictor of poor reading until kindergarten (5 years old). A 2016 meta-analysis by Snowling and Melby-Lervag found that the strongest predictor of an SLD in reading was poor grammar and speech articulation at ages 2 to 3 years, as well as grammar and vocabulary at 3 to 4 years. By 5 years old, phonologic processing and vocabulary most strongly predict reading delays, while most oral language difficulties have resolved at that point. From kindergarten and most of elementary school, a child with reading deficits will demonstrate a reluctance and resistance to reading aloud; will read hesitantly, slowly, and inaccurately, often with visible effort and discomfort (e.g., sighing, squirming, becoming flushed). They will also make guesses based on the sound of the first letter; they may recognize a few words by sight, but they are unable to “sound out” unfamiliar words. They will struggle to reconstruct the word having sounded out its component parts (e.g., sounds out /b/ /a/ /n/ /k/, yet cannot reconstitute to “bank”); adolescents and adults may read accurately but so slowly and with such effort that reading is not functional for everyday use, and so may avoid reading.

Lack of automaticity in letter–sound mapping not only interferes with reading at the word level, but will also make it difficult for the person to understand what has just been read at the level of the sentence, paragraph, or entire text. However, some individuals with SLD in reading at the word level may have very little difficulty in comprehending connected text (sentence, paragraph, entire text) if the need to decode words is bypassed by having the text read aloud at a reasonable pace (e.g., by using text–speech software).

These observable behaviors are due to an underlying difficulty in learning how the letters (graphemes) and speech sounds (phonemes) of one’s language map onto one another and being able to do so automatically. The general consensus in the scientific community is that the problems with letter–sound conversion arise from an underlying deficit in processing phonemes—the elementary constituents of speech sounds.

Common features of SLD in reading comprehension include reading text aloud with a flat intonation and no modulation to acknowledge punctuation marks (e.g., no pauses at commas or periods; no change in pitch to represent a question mark or exclamation point); may read the text accurately and fluently—often too fast—but is unable to extract and use the inherent meaning (e.g., may not grasp the sequence of events, relationships among events or people, may not be able to draw inferences from text or process the deeper meaning of the text); tends to simply reread the text without using effective strategies before restarting to read (e.g., does not predict, scan for or review unfamiliar words), during reading (e.g., does not make notes or self-question to check one’s understanding; does not create visual images of the scenarios), and after reading (e.g., does not check the accuracy of understanding; does not make a synopsis).

Over time, these challenges in reading comprehension tend to result in a reduction in or avoidance of reading print (e.g., newspapers, novels, nonfiction, lengthy texts regardless of format, such as digital or paper). In turn, restrictions on the amount of reading will have a negative impact on vocabulary growth so that the individual’s range of vocabulary use and understanding is noticeably reduced.

Signs and Symptoms of SLD in Written Expression. One of the most common clinical features is the noticeable and persistent poor spelling for age—often described as “atrocious spelling” (e.g., often adds, omits, or substitutes vowels and consonants; may spell phonetically but incorrectly, such as “pikchr” for “picture”). Sentences are often very short or incomplete and contain grammatical errors, omission of words, little or no use of punctuation, as well as spelling errors. Also, written paragraphs are often short, poorly constructed, and organized (e.g., does use a starting sentence to introduce the topic; includes several topics in one paragraph without a logical order; does not maintain the correct verb tense, incorrect use of pronouns) and their intended meaning is unclear. A common complaint from teachers (and parents) is “procrastination”: The youngster fails to start writing, writes very little, and with great effort and reluctance. In general, the person’s written work does not accurately reflect that individual’s knowledge, creativity, or depth of understanding of an issue: The person’s spoken or visual presentations are often very much better than the written one. Also, essential written activities, such as note-taking, pose major challenges. This is because note-taking requires the physical act of writing or typing notes to occur simultaneously with a complex web of other cognitive processes involved in listening, comprehending, and retaining key information while continuing to process incoming and new information and summarizing key points in a legible and organized format.

Signs and Symptoms of SLD in Mathematics. One common sign that persists across the lifespan is the sole reliance on finger counting for simple addition and subtraction, which is inappropriate for age. Note that typically, children start to switch from finger counting to more efficient calculation strategies, such as retrieval of math facts from memory, by about age 8 or 9 (e.g., see the interview of an accomplished author and Defense correspondent, describe his lifelong struggles with SLD in mathematics, including his use of finger counting under the boardroom table! http://www.mathematicalbrain.com/qt/paul.mov).

Other common features include a poor sense of numbers in terms of their magnitude and relationship; inaccurate counting and calculation; failure to attend to key mathematical symbols (e.g., symbols for addition, subtraction, multiplication, and division); difficulty with identifying the previous or next item in a sequence (e.g., difficulty identifying the name of previous or next day, month, or number, despite being able to rote list those items); difficulty understanding the concept and use of “zero” or decimal points; and “gets lost” in the middle of multidigit calculation and may switch procedures or apply them incorrectly (e.g., in the problem 57−38, may start to subtract 7 from 8 instead of 8 from 7, then either subtracts 3 from 5 without considering the trading procedure, or may switch to adding 5 and 3). Many struggle with understanding the “language” of mathematics, especially in *word problems*, that are emphasized in current curricula across all grade levels. Word problems consist of two interwoven semiotic layers: A narrative about some event or sequence of events in the real world, and a latent web of mathematical relations typically expressed in words, and related by a question involving concepts of quantity such as “more,” “more than,” “less than,” “altogether.” Thus, many individuals with SLD in reading have great difficulty with the language-based demands of word problems. Moreover, older children, adolescents, and adults manifest difficulty understanding and using money, telling the time, using calculators, and remembering numerical PIN codes.

Math anxiety is another common feature that persists across the lifespan. Often described as “a feeling of tension, apprehension, or fear that interferes with math performance,” it may manifest as sweaty palms, a racing pulse, breaking out in a cold sweat, or a choking feeling in the back of the throat, when required to perform mathematics in everyday life (e.g., answer math questions in class; complete math homework, counting out money to buy something, splitting a restaurant bill or calculating the tip, entering specific numbers for cash withdrawal or deposit at an ATM machine).

General Signs and Symptoms of SLD. In school-aged children, the typical presenting problem concerns the difficulty in learning at school ("not doing well at school—and we don't know why"). The puzzling picture for parents and teachers is that the child appears intelligent and often succeeds or even excels in other aspects of the curriculum (e.g., oral discussions, art, drama, sports) that do not depend on the core academic skills.

In addition to the domain-specific features summarized above, SLD imposes a great emotional toll. For example, other common features include embarrassment and low self-esteem, and extreme discomfort or even refusal when asked to read, write, or spell. Children and adolescents may be reluctant or refuse to go to school; may report being exposed to daily criticism, taunting, or bullying; may look anxious, stressed, sad, depressed, or express despair or suicidal ideation.

Associated Problems

SLD is commonly, but not invariably, associated with a developmental history of problems in speech and language, attention, and motor skills. Moreover, SLD commonly, but not invariably, co-occurs with other neurodevelopmental (e.g., Communication Disorders, ADHD) and mental health disorders (e.g., Anxiety and Mood Disorders). These associated problems are clinically important because the diagnosis of SLD cannot be confirmed until the child has started school and been exposed to formal academic instruction, but Communication Disorders in particular are likely to be apparent and diagnosed earlier and so indicate a risk for later SLD. Likewise, a developmental and family history of SLD may indicate a risk for later anxiety and mood disorders in adolescence and adulthood.

Speech and Language Impairments. Oral language constitutes an essential foundation for abilities in written language. Thus, it is not surprising that a developmental history of Communication Disorders (Speech Sound Disorder, Specific Language Impairments (SLI), alone or in combination) in preschool years is a common precursor of SLD, particularly for poor skills in reading words and reading comprehension, spelling, arithmetic fact retrieval, and calculation. Speech sound disorder, defined as problems in producing sounds in one’s language accurately and intelligibly, whereas language impairments refer to problems in developing the structural aspects of language, such as grammar (syntax) and vocabulary (semantics). For example, one longitudinal study of a community-based sample of children identified with pervasive speech/language disorders in kindergarten found an estimated three- to sixfold greater risk for SLD (all manifestations alone or in combination) in young adulthood compared to typically developing youngsters. Moreover, according to a recent population-based study, the cumulative risk of SLD in written language by age 19 is about 64% in youngsters with speech/language impairments compared to 18% in those without.

Attention-Deficit/Hyperactivity Disorder. Epidemiologic and clinical studies indicate that the overlap between SLD and ADHD is greater than expected by chance alone. For example, around 20% to 45% of children with ADHD also meet diagnostic criteria for SLD, but the strongest link appears to be between the inattention dimension of ADHD and SLD, particularly SLD in reading and writing. Inattention in the classroom (even at subclinical levels), as rated by teachers, is a robust predictor of concurrent and subsequent poor academic outcomes, as well as a poor response to evidence-based academic intervention. Importantly, there is little robust evidence that medication treatment for ADHD (including stimulant and nonstimulant medications) has any substantial effect on SLD, despite its positive effects on the behavioral symptoms of ADHD and academic productivity (i.e., completing more arithmetic problems in a specified time frame). By contrast, preliminary evidence suggests that intensive educational intervention may improve (but not normalize) the behavioral problems. The clinical implications of these findings are that assessment for SLD should include assessment for ADHD and vice versa: Youngsters with SLD who have coexisting inattention or ADHD require multimodal intervention, including intensive educational intervention, since medication for ADHD will not address the SLD and intervention for SLD will be less effective if the inattention remains unaddressed.

Emotional Problems, Anxiety and Mood Disorders, Suicide Risk. Individuals with SLD are highly likely to manifest concurrent social, emotional, and mental health problems. For example, they are only too aware of their academic difficulties, leading to low self-esteem and these negative self-perceptions are very difficult to change and contribute to their problems in social and academic functioning. Avoidance of or reluctance to engage in activities requiring academic skills is common in children, adolescents, and adults. Also, recent meta-analyses confirm that the majority of youngsters with SLD (about 70%) have higher rates of anxiety and depressive symptoms compared to non-SLD peers. Episodes of severe anxiety or anxiety disorders (including somatic complaints or panic attacks) are common across the lifespan and accompany both the circumscribed and broader expression of learning difficulties. Moreover, SLD is associated with an increased risk for suicidal ideation and suicide attempts in children, adolescents, and adults. The co-occurrence of internalizing symptoms and disorders is clinically significant, whereas SLD is treated primarily in the field of education; thus, these internalizing symptoms often remain unaddressed. Thus psychiatrists and other mental health practitioners play an important role in identifying, monitoring, and treating concurrent internalizing problems.

Criteria for Diagnosis

There are no biomarkers to date for SLD. Thus, SLD is a clinical diagnosis, which is best made by an experienced clinician, based on a comprehensive assessment with careful clinical synthesis of information from multiple sources, including developmental, medical, educational, and family history; school reports; teacher observations, including response to classroom instruction and other intervention provided at school; as well as direct standardized psychometric assessment of the individual's academic skills—including reading (accuracy, fluency, comprehension), spelling, written expression, and arithmetic (number sense, counting, algorithmic computation). The DSM-5 diagnostic criteria for SLD are presented in Table 40–3.

Table 40–3.

DSM-5 Diagnostic Criteria for Specific Learning Disorder, With ICD-9-CM Codes (ICD-10 Codes Are Shown Parenthetically)

Diagnostic Criteria

A. Difficulties learning and using academic skills, as indicated by the presence of at least one of the following symptoms that have persisted for at least 6 months, despite the provision of intervention that targets those difficulties:
    1. Inaccurate or slow and effortful word reading (e.g., reads single words aloud incorrectly or slowly and hesitantly, frequently guesses words, difficulties sounding out words)
    2. Difficulty understanding the meaning of what is read (e.g., may read text accurately but not understand the sequence, relationships, inferences, or deeper meanings of what is read)
    3. Difficulties with spelling (e.g., may add, omit, or substitute vowels or consonants)
    4. Difficulties with written expression (e.g., makes multiple grammatical or punctuation errors within sentences; employs poor paragraph organization; written expression of ideas lacks clarity)
    5. Difficulties mastering number sense, number facts, or calculation (e.g., poor understanding of numbers, their magnitude, and relationships; counts on fingers to add single-digit numbers instead of recalling the math fact like peers; gets lost in the midst of arithmetic computation and may switch procedures)
    6. Difficulties with mathematical reasoning (e.g., severe difficulty applying mathematical concepts, facts, or procedures to solve quantitative problems)

B. The affected academic skills are substantially and quantifiably below those expected for the individual’s chronologic age and cause significant interference with academic or occupational performance, or activities of daily living, as confirmed by individually administered standardized achievement measures and comprehensive clinical assessment. For individuals aged 17 years and older, a documented history of impairing learning difficulties may be substituted for the standardized assessment

C. The learning difficulties begin during school-age years but may not become fully manifest until the demands for those affected academic skills exceed the individual’s limited capacities (e.g., as in timed tests, reading or writing lengthy complex reports for a tight deadline, excessively heavy academic loads)

D. The learning difficulties are not better accounted for by Intellectual Disabilities, uncorrected visual or auditory acuity, other mental or neurologic disorders, psychosocial adversity, lack of proficiency in the language of academic instruction, or inadequate educational instruction.

Note: The four diagnostic criteria are to be met based on a clinical synthesis of the individual’s history (developmental, medical, family, educational), school reports, and psychoeducational assessment.

Coding Note: Specify all academic domains and subskills that are impaired. When more than one domain is impaired, each one should be coded individually according to the following specifiers.

Specify if:

315.00 (F81.0) With impairment in reading:

Word reading accuracy

Reading rate or fluency

Reading comprehension

Note: *Dyslexia* is an alternative term used to refer to a pattern of learning difficulties characterized by problems with accurate or fluent word recognition, poor decoding, and poor spelling abilities. If dyslexia is used to specify this particular pattern of difficulties, it is important also to specify any additional difficulties that are present, such as difficulties with reading comprehension or math reasoning.

315.2 (F81.81) With impairment in written expression:

Spelling accuracy

Grammar and punctuation accuracy

Clarity or organization of written expression

315.1 (F81.2) With impairment in mathematics:

Number sense
Memorization of arithmetic facts
Accurate or fluent calculation
Accurate math reasoning

Note: *Dyscalculia* is an alternative term used to refer to a pattern of difficulties characterized by problems processing numerical information, learning arithmetic facts, and performing accurate or fluent calculations. If dyscalculia is used to specify this particular pattern of mathematic difficulties, it is important to also specify any additional difficulties that are present, such as difficulties with math reasoning or word reasoning accuracy.

Specify current severity:

Mild: Some difficulties learning skills in one or two academic domains, but may be of mild enough severity that the individual may be able to compensate or function well when provided with appropriate accommodations or support services, especially during the school years.

Moderate: Marked difficulties learning skills in one or more academic domains, so that the individual is unlikely to become proficient without some intervals of intensive and specialized teaching during the school years. Some accommodations or supportive services at least part of the day at school, workplace, or at home may be needed to complete activities accurately and efficiently.

Severe: Severe difficulties learning skills, affecting several academic domains, so that the individual is unlikely to learn those skills without ongoing intensive individualized and specialized teaching for most of the school years. Even with an array of appropriate accommodations or services at home, school, or workplace, the individual may not be able to complete all activities efficiently.

This diagnostic category is indicated by using one overarching term, “Specific Learning Disorder,” which incorporates difficulties in learning academic skills, such as reading, writing, and mathematics, which were classified as separate disorders in previous versions of DSM and in ICD-10. The generic term reflects the evidence from behavior–genetic studies showing that learning difficulties in the various academic domains share genetic variance and from clinical and epidemiologic studies that individuals showing a deficit in one academic domain frequently show deficits in other domains as well, although deficits isolated to one academic domain may occur. Using this overarching term, diagnosticians can then specify the details of the areas of learning difficulty and their severity as manifest at the time of assessment.

The manifestation of learning difficulties *at the time of assessment* is coded by adding *Specifiers* to the generic diagnosis of SLD to provide more precise information about the domains that are affected. Specifiers are deficits in reading, deficits in writing, deficits in mathematics, each of which can be further specified by detailed descriptions (e.g., SLD with impairment in reading [currently manifests as problems in word reading accuracy, reading fluency, and comprehension] and impairment in mathematics [currently manifests as problems with memorization of math facts, as well as in accuracy of calculation]). Use of the terms “dyslexia” and “dyscalculia” to refer to problems in learning to read or do arithmetic, respectively, is permitted according to clinician and patient preference, but detailed coding of the manifestation of SLD should still be completed. Severity ratings (mild, moderate, severe), which reflect the dimensional nature of SLD, permit further description by considering the range of learning difficulties and impairments, as well as the likely need for accommodations and support to best promote ongoing learning. DSM-5 specifies a set of four diagnostic criteria, all of which must be met to confirm a clinical diagnosis of SLD.

Criterion A. This criterion lists a range of observable descriptive behaviors or symptoms (Criterion A1 to A6, Table 40–3) which may be observed, probed during the clinical assessment, and confirmed by evidence from the school reports, teacher observations or ratings, previous psychoeducational assessment reports, and current performance scores on standardized achievement tests. At least one of these symptoms must be present. Moreover, Criterion A also requires evidence that the symptoms have persisted for at least 6 months despite the provision of intervention that targets each of the affected academic domains. For children, the term "*persistent*" is confirmed by the evidence of restricted progress in mastering the affected academic skill, over at least 6 months, despite the provision of intervention that targets that affected skill. For older adolescents and adults, persistent difficulties refer to ongoing difficulties with literacy or numeracy skills that first manifest during the school years, as confirmed by school reports, evaluated portfolios of past and current work, or previous assessments.

The term "*intervention*" refers to extra help at school or home, small group or individualized instruction, using any instructional approaches available at the school that focus on the affected skill. DSM-5 does not require the provision of intensive evidence-based (research-based) intervention—as specified by a current educational model in the United States (Response-to-Intervention [RTI]). RTI is a multitiered approach to academic and behavioral intervention designed to provide early, systematic, and appropriately intensive assistance to children who are at risk or already underperforming academically or behaviorally, compared to grade-appropriate standards. To date, the RTI approach, while laudable in its goals, not only lacks a strong evidence base but also is not consistently available within the United States and is rarely available outside of the United States.

Criterion B. This comprises two components: (i) academic achievement that is well below average and (ii) impairment resulting from the learning difficulties. In terms of low academic achievement, the DSM-5 applies the "average-person standard" that has been applied in disability discrimination laws for years. An individual's scores on standardized, individually administered, culturally sensitive academic achievement tests are compared to the population mean for chronologic age, not to IQ or to achievement scores of subsets of the population, such as peers attending university, medical, or law school. Examples of commonly used standard achievement tests are shown in Table 40–4.

DSM-5 does not specify what cut-off scores to use for determining low academic achievement within the diagnostic criterion itself, but provides guidelines within the text. One suggested guideline for below-average academic performance is to require evidence that scores on standardized academic achievement tests fall at least 1.5 standard deviations below the general population mean for age: This cut-off score is equivalent to a standard score >78 or >7th percentile. Standardized tests vary in the number and composition of items relevant to age, as well as in the particular aspect of reading, arithmetic, spelling, and written expression. Moreover, it is important to recall that standardized testing occurs in rather artificial situations (quiet space, minimal noise or other distractions, use of a standardized procedure that often precludes repetition of a question by the examiner), and performance may be influenced by factors other than academic skill level, such as motivation and effort, familiarity with the testing situation, anxiety, hunger, and sleep status, etc. Thus, greater diagnostic certainty is established by the evidence of low scores on more than one test or subtest.

A second guideline suggests that more lenient cut-off scores may be used (1.0 to 1.5 standard deviations below mean for age) when supported by other converging evidence of learning difficulties, such as academic history, other test scores, school reports, teacher observations, etc.

For individuals aged 17 and older, a documented history of long-standing and impairing learning difficulties (based on self-reported history of difficulties learning to read, spell, do arithmetic or written work; previous standardized testing; school reports; previous systematic clinical assessments for SLD) may be substituted for the standardized assessment. The goal of this substitution is to avoid the time and expense needed for unnecessary repeated standardized assessments, based on the evidence that childhood-onset SLD typically persists into adulthood.

Identification of SLD in individuals in postsecondary education poses challenges. DSM-5 does not preclude the possibility that an individual with high IQ, giftedness, or attending postsecondary education may have SLD. Evidence required for greater diagnostic certainty in this situation includes previous or current reports (from school, significant others), self-reported history of marked learning difficulties, a manifestation of self-report of an extraordinary effort required or dependence on the provision of support and accommodations needed to attain/maintain performance; previously evaluated portfolios of academic work; previous clinical assessments indicating SLD; family history of SLD; or current evidence of low academic scores (e.g., below the population mean for age). Extensive testing is rarely required: Research evidence indicates that tests of fluent word reading, reading comprehension, word spelling, number sense, and fluency of arithmetic computation suffice.

In the absence of available culturally appropriate and normed standardized academic achievement tests (as occurs in many low- to middle-income countries or non–English-speaking countries), converging evidence of markedly low academic performance must be derived from careful clinical review of scores on locally available tests, school reports, and clinical assessment. (See Tables 40–1 to 40–4 for a description of commonly used tests.)

Table 40–4.

Examples of Commonly Used Standardized Tests of Reading, Written Expression, Arithmetic, and Related Skills

Name of Standardized Test	Reading Skills
Comprehensive Test of Phonologic Processing (CTOPP); standardized. Ages: 5 years to young adulthood	Basic reading skills (e.g., phonologic awareness, phonologic coding, working memory, rapid naming)
Woodcock Johnson-III Achievement battery	Letter–word identification, word attack, and reading fluency reading comprehension
Test of Word Reading Efficiency (TOWRE); Ages: 5 years to young adulthood	Single-word reading efficiency (e.g., speedy and accurate naming of single words and pseudowords)
Gray Oral Reading Test; Nelson–Denny Reading Test; Gray Silent Reading Test	Reading fluency and comprehension (e.g., rate of reading connected text for meaning)
	Written Expression Skills
Wechsler Individual Achievement Test (WIAT-II) Ages: 5–19 years	Spelling, written expression
Test of Written Language (TOWL; 3rd edition) Ages: 7.5–17.9 years	1. Elicited writing, including vocabulary, spelling, capitalization and punctuation, logical sentences, and sentence combining 2. Spontaneous writing combining
Test of Early Written Language (TEWL; 2nd edition) Ages: 3–11 years	Basic, global, and contextual writing
Test of Written Spelling (TOWS;	Spelling of phonetically regular

4th edition) Ages 6–18 years	and nonregular words
Woodcock–Johnson Psychoeducational Battery Ages: 5 years–adult	Dictation, proofing, writing fluency, writing samples
	Mathematics Skills
Woodcock–Johnson Achievement Battery-III	Math fluency, calculation, quantitative concepts, applied problems
Test of Early Mathematical Abilities—3rd edition Age: 3–0 to 8–11	Numbering skills, number-comparison facility, numeral literacy, mastery of number facts, calculation skills, and understanding of concepts
Test of Mathematical Abilities Age: 8–0 to 18–11	Mathematical symbols and concepts; computation; mathematics in everyday life; word problems; attitude toward math
Teacher Academic Attainment Scale (TAAS)	Subjective rating scale of student academic achievement (7 items)
Math Anxiety Questionnaire	Math anxiety
Abbreviated Math Anxiety Scale	1. Learning anxiety: anxiety related to learning math 2. Testing: anxiety related to being tested in math
Subjective Numeracy Scale	Subjective rating of one's health numeracy
Test of Functional Health Literacy in Adults (s-TOFHLA)	Objective measure of health literacy
Rapid Estimate of	Objective measure of health

Adult/Adolescent Literacy in Medicine (REALM)	literacy

Moreover, Criterion B emphasizes impairment, in requiring that the learning difficulties cause significant impairment in academic, occupational, social functioning, or in activities in daily living that requires academic skills. Thus, low academic scores per se are not sufficient to meet the specifications of Criterion B: Evidence of associated impairment is required. This component is in line with the standard of the U.S. “Americans with Disabilities Act (ADA)” for determining a disability.

Criterion C. This third criterion requires evidence that the symptoms of SLD manifest in the school years—most reliably interpreted as during the elementary (primary) school years. Symptoms of SLD may manifest in preschool years, but a diagnosis cannot be confirmed until the individual has received formal instruction in the core academic skills. However, a diagnosis of SLD can be made for the first time in adolescence or adulthood. This is because the manifest learning difficulties may have been overlooked, not assessed, or attributed solely to concurrent emotional behavioral difficulties. Also, some individuals (particularly those with higher adaptive and intellectual functioning, or in highly supportive environments) may have coped with the demands for the core academic skills during the school years, albeit by putting forth extraordinary effort, or by using compensatory skills, that no longer suffice in later years, when high demands on accurate and fluent academic skills (e.g., reading or writing lengthy complex reports for a tight deadline, excessively heavy academic or occupational loads) start to exceed the individual’s limited capacities and compensatory mechanisms. In such cases, greater diagnostic certainty is established by converging evidence from comprehensive clinical assessment, and the ability to rule out loss of previously acquired academic skills as a result of a major medical event or condition.

Criterion D. The fourth criterion refers to a range of exclusionary conditions. These include intellectual disability, other major mental or neurologic conditions, uncorrected visual or auditory acuity, severe psychosocial adversity, lack of proficiency in the language of instruction (for adults, lack of proficiency in the language of the workplace or social community), lack of or inadequate educational instruction, as may occur for children excluded from education for various reasons (e.g., because they are girls; living in war zones, no schools, no teachers, etc.). These exclusionary criteria are evaluated by means of a comprehensive clinical assessment.

As of 2012, UNICEF reports that about 58 million children are excluded from primary school education and 63 million from lower secondary school education (http://www.uis.unesco.org/Education/Pages/out-of-school-children.aspx). Certainly, it makes no sense to make a diagnosis of SLD in immigrant children who previously have been excluded from education. The issue of excluding from the SLD category those children whose low academic scores may be due to instructional factors (inadequate instruction; a limited opportunity to learn) is important but has been challenging for clinicians to operationalize. One component of Criterion A attempts to address this challenge by requiring evidence that symptoms of learning difficulties have persisted for at least 6 months despite the provision of intervention that targets the affected academic skills. As noted previously, the RTI approach was not adopted by DSM-5 due to insufficient evidence, and lack of universal availability of RTI approaches. However, in many countries, the quality of teacher training has improved over recent years (especially in teaching children to read), affording some assurance that a student’s limited progress is not due to inadequate instruction, so SLD is a possibility.

Identification of SLD in individuals whose first language (mother tongue) differs from the language of instruction is challenging. Greater diagnostic certainty is accorded by evidence of the following: The individual has a history of language delay or disability in the native language; the individual has had difficulty developing literacy or numeracy skills in the native language (assuming adequate instruction in the native language); there is a family history of SLD in parents, siblings, or other close relatives, the individual is not making adequate progress over 6 months compared to other nonnative speakers, despite the provision of targeted intervention.

Does Information from Tests of Intellectual Capacity or Cognitive Processing Assist in the Diagnosis of SLD or Guide Educational Treatment?

Intelligence testing (and IQ profiling using various subtests) with the requirement for a significant discrepancy between intellectual and academic achievement has been the primary and often sole criterion for the diagnosis of SLD in previous versions of the DSM, continues to be used internationally to determine eligibility for special education services and accommodations, and figures strongly in the understanding of SLD by various stakeholder groups (e.g., teachers, psychologists, parents and parent organizations, lobby groups and researchers). Moreover, this “discrepancy” model has become ingrained in clinical training and practice, despite the several decades of research evidence against its validity for diagnosis or utility in guiding educational instruction. For example, discrepancy scores are unreliable, and children with learning difficulties who do and do not meet the IQ-achievement discrepancy do not differ in symptomatology, associated cognitive deficits, or response to intervention. In other words, the purported differences between those with discrepant and nondiscrepant IQ-achievement scores have not proven to be clinically or educationally meaningful. Thus, a measure of intelligence is not required for a diagnosis of SLD (unless there are concerns about the individual’s intellectual ability and adaptive behavior).

Accordingly, based on the available scientific evidence, DSM-5 eliminated the requirement for a significant discrepancy between the IQ score and an achievement score for the diagnosis of SLD. The DSM-5 does not prohibit the inclusion of intellectual assessment in the diagnostic assessment of SLD. Occasionally, information from an IQ test might be helpful in changing a teacher or parent’s overall view of the child and their misunderstanding of the child's intellectual ability. However, when formulating a diagnosis of SLD, clinicians should also keep in mind the DSM-5 changes to the conceptualization and criteria for Intellectual Disability: Specifically, poor adaptive and intellectual functioning, with the latter suggested by IQ score less than 70 ± 5 standard points. This means that individuals with an IQ score of greater than 70 ± 5 standard points and adequate adaptive functioning could potentially—but not necessarily—meet the criteria for SLD since the differential diagnosis of Intellectual Disability can be ruled out.

In recent years, testing of cognitive processes (e.g., phonologic processing, rapid automatized naming, auditory and visual processing, processing speed) and executive functions (e.g., working memory, inhibitory control, cognitive flexibility, sustained attention) has been incorporated increasingly in assessment for SLD, in addition to IQ testing. The goal of such testing is to document patterns of cognitive strengths and weaknesses to inform the development of differentiated and more effective educational instruction and intervention. However, it is unclear whether the relationship between SLD and these processes or executive functions is causal or correlational. There is little or no robust evidence that training these cognitive processes and executive functions will boost academic learning particularly in students with SLD. Also, recent meta-analyses conclude that effect sizes of the magnitude of the relationship between children's cognitive characteristics and response to intervention were small and unable to improve clinical prediction from measures of academic skills per se. Moreover, there is little evidence that cognitive profiles are valuable for planning intervention (i.e., little evidence for Aptitude X Treatment interactions). Thus current recommendations are for assessment and intervention for SLD to focus on educational rather than cognitive factors—a position that is understandably threatening to clinicians and other professionals trained in the psychometric tradition and who might lack expertise in curricular and pedagogical practices. Hence the DSM-5 criterion B does require the use of individually administered standardized tests of academic achievement in reading, writing, and arithmetic, where possible.

DIFFERENTIAL DIAGNOSIS

SLD can be distinguished from normal variation (individual differences) in learning academic skills due to other internal and external factors by the severity of the learning difficulties, the specificity of the difficulties in the presence of intact intellectual abilities, and their persistence in the presence of adequate educational opportunity and receipt of the same instruction as the peer group, targeted home or school-based intervention, competency in the language of instruction (even when different from one's mother tongue).

A diagnosis of SLD is not usually made before the child is about 7 years old because evidence of failure to learn to read, write, or do arithmetic is required. Difficulties in learning foundational academic skills may occur for a variety of reasons (e.g., lack of adequate exposure to print, limited education) and are associated with numerous mental health conditions, including mental retardation, developmental coordination disorder, communication disorders, ADHD, conduct disorder, hearing or visual problems, and prematurity. The most common distinguishing feature of SLD in reading is a persistent impairment in phonologic processing and spelling; that of SLD in mathematics is a persistent impairment in number facts. In a child with visual or hearing deficits, the learning problems must be in excess of the difficulty typically associated with these sensory disorders. In a child with learning difficulties in the presence of low intellectual abilities (i.e., an IQ score of 70 ± 5), it is important to assess adaptive behavior to be able to rule out Intellectual Disabilities.

SLD is distinct from Intellectual Disabilities: Individuals diagnosed with intellectual disability have reduced cognitive capacity that has a global impact on learning and adaptive functioning in everyday life. By contrast, individuals with a diagnosis of SLD have at least average intellectual capacity but exhibit significant difficulties in one or more *academic* areas, while coping well or even excelling in other areas of academic, sporting, or artistic achievement. Moreover, SLD is distinguished from “learning difficulties,” which is a broader term that encompasses difficulties learning as a consequence of a range of causes, including intellectual disabilities, physical or sensory deficits (e.g., hearing or visual impairments), emotional or behavioral difficulties, inadequate environmental experiences, or appropriate educational opportunities.

SLD in Reading, Mathematics, or Written Expression is frequently associated with ADHD, and a concurrent diagnosis is not only permissible but is also essential. An explicit statement should be made concerning the presence of both clinical conditions to ensure that the child can access relevant and effective interventions. Moreover, even if the individual does not meet the full criteria for ADHD but does manifest persistent symptoms of inattention (particularly in the school setting), clinicians should report these problems, given the increased risk conferred for poor response to intervention if inattention is not targeted in the treatment plan.

It might be possible to determine inadequate instruction as the primary explanation for reading problems through detailed interview with parents and teachers. Probes for the number of schools attended, absenteeism (voluntary due to illness or vacation; required due to class or school suspensions and expulsions), and type of reading instruction provided at the school(s) in the primary grades may be informative. However, differential diagnosis may be complicated by parental history or current manifestation of SLD, given that parents with SLD would be less likely to be able to provide the necessary early reading or numerical experiences for the child.

COURSE AND PROGNOSIS

Converging evidence indicates that SLD is persistent and does not remit with increasing age in the absence of effective intervention. SLD tends to be a persistent and chronic condition that remains with the individual his or her entire life, albeit with developmental changes in its manifestation.

Onset, recognition, and diagnosis of SLD usually occurs during the first few years of elementary school when children are expected to learn to read, write, spell, and do basic arithmetic. Precursor signs (e.g., delayed onset of talking; difficulties with counting or rhyming; problems with fine motor skills required for writing) commonly occur in preschool years before the start of formal schooling. Moreover, preschoolers with poor phonologic short-term memory (STM) skills and specific language impairment (SLI) are highly likely to meet diagnostic criteria for SLD in reading at school age. However, referral and formal diagnosis rarely occurs until a couple of years later in second grade, when the children have failed to respond to formal classroom instruction in reading.

SLD in elementary school–aged children (grades 1 to 3) typically manifests first as marked difficulty learning to connect letters with the sounds they make (particularly in English-speaking children), to recognize and read common one-syllable words (e.g., mat, top) or common but irregularly spelled words (e.g., said, two). Reading aloud is slow, inaccurate, and effortful. Some children may also (or instead) show problems in learning to count, remember math facts, and perform simple single-digit arithmetic. Recent evidence suggested that it is possible to estimate an individual child’s risk for SLD in reading at school age from the following factors measured in preschool years (age 3.5 years): Familial history of reading problems, poor grammar and speech articulation, poor letter and object naming speeds, and poor phonologic awareness.

In the middle grades (grades 4 to 6), children with SLD may not only continue to show problems with word reading and basic number sense but also may manifest problems with spelling, writing, and understanding word problems in mathematics. Others may gradually be able to sound out words, but their reading is slow and effortful, they have difficulty understanding what they have just read, and also problems start to manifest in their written work (e.g., poor spelling, poor punctuation, words left out of sentences, short, disconnected sentences, illegible and disorganized writing). Some youngsters continue to count on their fingers since they cannot remember math facts. It is not uncommon, even at this young age, for children to dread going to school or to try to avoid reading, writing, or arithmetic.

By adolescence, some youngsters may show improved word recognition and the ability to sound out words, but reading remains slow and effortful, often with poor comprehension, and so they cannot keep up with the increasing demands for reading complex material. They often need to reread material to get even the main point and have great difficulty making inferences from written text. Written work is markedly impoverished: numerous spelling errors, illegible writing, with poor sentence, and paragraph structure. Those who showed problems in basic number sense at a younger age may use long and inefficient strategies to work out even simple arithmetic, such as “7 × 8” (e.g., draw 8 groups of 7 items, and then counting all of the items). Ongoing dread of and failure in school may result in high-school dropout, anxiety, and depression.

A longitudinal investigation of a 1990 U.S. cohort of children reveals that individuals with SLD in word reading (a.k.a., dyslexia) show an achievement gap in reading that is discernible upon school entry in grade 1 (about age 6) and that persists throughout childhood and adolescence. A more recent study by Shaywitz et al., in 2015, examined 414 students from the Connecticut Longitudinal Study to determine if differences between dyslexic and typical readers in their reading scores and verbal IQ are evident as early as first grade, as well as whether the trajectory of these differences is seen throughout adolescence. The study found that a significant achievement gap was evident as early as first grade, and the gap persisted into middle and high school. It remains unknown whether early reading intervention (i.e., kindergarten, grade 1) will eliminate the observed persistent difference in growth trajectories in reading. Likewise, a longitudinal investigation of a large sample of kindergarten children recruited from 1998 to 1999 and followed through 8th grade revealed that children with SLD in mathematics enter kindergarten with lower skill levels, and the achievement gap persists through grade 8.

Young adults with persistent problems in both reading accuracy and fluency appear to develop compensatory mechanisms to cope with reading, such as greater reliance on memory-based rather than analytic strategies to assist in word identification. By adulthood, many individuals try to hide the fact that they cannot read, spell, or do arithmetic by avoiding both leisure and work-related activities that require these skills, or use alternative approaches to access print (e.g., text-to-speech or speech-to-text software, audiobooks, audiovisual media).

The clinical course of SLD is often complicated further by comorbidity with other mental health problems, such as ADHD or conduct disorder, as well as with low self-esteem, anxiety, depression, and increased risk for suicidal ideation and suicide attempts. The causal relationships between SLD and the various comorbid disorders are unknown and longitudinal epidemiologic studies suggest that the relationships are complex.

On a more positive note, a recent study reported that adults with SLD in reading (a.k.a., “dyslexia”) are overrepresented among entrepreneurs and manifest higher levels of visual problem-solving skills compared to peers with average reading abilities. This subgroup of individuals attributed their success to an admixture of high self-motivation, educational accommodations, and a supportive social network, particularly parents.

Juan P, a 20-year-old Hispanic college student, presented at the primary care clinic in his home city, with complaints of increasing problems sleeping, inability to concentrate or manage his college schedule, failing some courses, and feeling “down” most days. Clinical history indicated a normal birth, slowness in learning to talk, childhood problems with concentration, hyperactivity and angry outbursts, as well as struggles learning to read, at school. Family history was positive for ADHD (older brother) and SLD (father, now deceased, was reported to have had “dyslexia” and dropped out of school early). He had been diagnosed with ADHD, Predominantly Combined Type, at age 9, but did not meet criteria for SLD, since the discrepancy between his intellectual capacity and reading achievement was deemed not to be “substantial” as required by DSM-IV and his local school board.

During the clinical interview, JP reported that since starting college a year ago, he had been unable to remain focused while reading or listening to lectures, felt overwhelmed, and was unable to complete written assignments on time. He complained of feeling restless, agitated, exhausted, and often in a “blue mood.” He denied any substance use or suicidal thoughts. He stopped taking medication for ADHD when he was aged 12 and had not sought registration with Student Disability Services at his college for help with his ADHD because he thought he could get through college by himself. The current psychoeducational assessment confirmed that JP’s reading fluency and comprehension, spelling, and written expression, were substantially and quantifiably below that expected for age and were causing significant impairment.

Diagnostic formulation: *Attention-Deficit/Hyperactivity Disorder*, with predominantly inattentive presentation, of mild to moderate severity; *Specific Learning Disorder*, with impairment in reading (fluency, comprehension) and written expression (spelling, organization of written expression), all currently of moderate severity; depressive symptoms but did not meet criteria for a mood disorder.

TREATMENT

Treatment focuses almost exclusively on academic intervention and rarely includes mental health services even though students with SLD experience higher levels of inattention (and ADHD), anxiety, and depression than their non-SLD peers. Moreover, treatment of SLD is typically carried out in education settings or specialized psychology clinics, and so is not the primary responsibility of psychiatrists or primary care providers.

The primary role of medical health care providers is that of coordinator, which, as a first step, includes the provision of psychoeducation about the disorder and its longer-term implications. Thus, physicians need to be able to explain what SLD is and refer parents (or the adult patient) to organizations, websites, or reading materials that will help (see the References for some useful websites). Also, parents may need help in understanding their child's needs and rights under the IDEA, including possible need for accommodations. Given that SLD tends to run in families, physicians may need to modify how any numeric health information is communicated (prevalence rates, risk ratios, dosage, etc.), as well as to check that the individual or caregivers are able to comprehend any relevant printed or website material.

A second critical step is to establish a monitoring plan with the patient and family, to permit early detection and management of commonly associated mental health problems, such as ADHD, anxiety, and depression, as well as to ascertain whether recommended accommodations have been put in place along with intensive, individualized, explicit instruction. Moreover, the need for transitional planning is essential to help individuals with SLD through major developmental and life transitions (e.g., transition from elementary to secondary school; from secondary school to the workforce or postsecondary education; marriage, parenthood, etc.) and facilitate access to services.

One of the major problems is that the standard instruction in regular classrooms is too little, too general, and nonsystematic. For example, one large-scale study found that children receiving special education over a 1-year period advanced in reading by only 0.04 standard deviations per year, which means that it would take at least 8 years to raise these students' scores from the 5th to the 9th percentile. By contrast, students with SLD in reading who received 1 to 2 hours daily of intense and focused intervention for a total of 35 to 70 hours of instruction showed dramatic gains in performance on standardized measures of both decoding and comprehension, which were maintained for several years after intervention. The instruction programs were very explicit and visible, conducted in small, interactive groups of children matched for reading abilities, which promoted engaged and repeated reading of connected text presented in a way that controlled task difficulty, and included instruction in basic reading abilities (e.g., teaching phoneme-to-grapheme correspondences), as well as the application of metacognitive strategies for decoding unfamiliar words and comprehending connected text. Of note, preliminary evidence suggests that intense and focused instruction may, in fact, alter the aberrant brain activation profiles observed in children with SLD. Thus, clinicians need to be aware that recommendations for placement in special education may not be sufficient to improve reading or arithmetic skills. Rather, they need to advocate for the provision of intense, focused, and explicit instruction in each of the affected academic domains.

Also, given the importance of literacy and numeracy skills in health, clinicians are advised to screen for and monitor health literacy and numeracy in all patients (and parents of pediatric patients), regardless of their referral problem. Low literacy or numeracy cannot be inferred reliably on the basis of the patient's education level, intelligence, or other observable behaviors. Reliable short screening forms can be used to assess health literacy and numeracy in adolescents and adults and to guide health communication.

Developmental Coordination Disorder

VIJAY VISHWANATH, M.D., PH.D., AND WENDY G. MITCHELL, M.D.

Developmental coordination disorder (DCD) is a neuromotor disability emerging in the early developmental period, which can affect both fine and gross motor skills, interfering with daily activities. Children with DCD have a motor performance that is typically slower, less accurate, and more variable than peers of the same age. DCD is estimated to occur in 5% to 6% of children aged 5 to 11 years, and 1.8% of children 7 years of age exhibit severe DCD. DCD affects boys more often than girls; most recent population studies report ratios of male:female of about 2:1. Children exhibiting DCD often show impairment in gross motor skills such as jumping, hopping, and running, fine motor skills, including handwriting, tying their shoelaces, or using utensils, and balance. Motor coordination disorder is comorbid up to 50% of the time with attention-deficit/hyperactivity disorder (ADHD). Other disorders that may co-occur with DCD are communication disorders and specific learning disorders. Delayed motor milestones may be the first sign of DCD in the absence of intellectual disability. Without intervention, DCD often continues to cause impairment throughout childhood and adolescence, leading to significant consequences physically, educationally, socially, and psychiatrically.

DEFINITION

The essential feature of DCD, according to DSM-5-TR, is impaired motor skills leading to deficits in coordination compared to children of the same chronologic age and intellectual level, interfering with activities of daily living, social activities, and school productivity. Key symptoms are marked delays in achieving motor milestones, such as walking, crawling, and sitting, constantly dropping objects, inability to catch or throw a ball, and poor handwriting. Children with DCD perform motor coordination tasks slower and less accurately than those peers of the same chronologic age and intellectual capacity. Specific manifestations of DCD are detailed in Table 41–1.

HISTORY

In the early 1900s, childhood motor clumsiness was termed *motor deficiency syndrome*. This syndrome was characterized by awkward voluntary actions, excessive tendon reflexes, mild hypertonicity, and neurologic overflow movement. The term *clumsy child syndrome* first appeared in the literature in the 1930s to describe a set of symptoms associated with clumsy motor behaviors of unknown etiology, not associated with a known neurologic disorder. The observation was made that many children with motor coordination difficulties also exhibited ADHD, communication disorders, and specific learning disorders. During the 1940s, remedial programs were established in an attempt to improve academic learning deficits through the treatment of coordination difficulties observed in children.

By the 1960s, *clumsy child syndrome* was officially distinguished from other categories of learning disorders. From this period to the mid-1980s, significant investigations were conducted into perceptual-sensory causes for motor impairments, as well as social and emotional problems associated with such impairments. Children with clumsy behavior were noted to have deficits rather than solely delayed fine and gross motor coordination skills.

COMPARATIVE NOSOLOGY

Many terms have historically been applied to the description of *clumsiness* in a child. Terms used in the past that overlap with a description of DCD include congenital maladroitness, choreiform syndrome, psychomotor syndrome, developmental apraxia, developmental dyspraxia, congenital clumsiness, developmental agnosia, and developmental dyspraxia–dysgnosia. It is only appropriate to make a diagnosis of DCD after any suspicion of a neurologic disorder is ruled out. In the DSM-5-TR, DCD is not diagnosed if symptoms are attributable to an intellectual developmental disorder or a neurologic condition such as cerebral palsy, muscular dystrophy, or a degenerative disorder. Although currently, this syndrome is still occasionally referred to as clumsy child syndrome, DCD and specific developmental disorder of motor function are more appropriate terms.

Table 41–1.
Manifestations of Developmental Coordination Disorder

Gross Motor Manifestations

Preschool age

Delays in reaching motor milestones, such as sitting, crawling, and walking

Balance problems: Falling, getting bruised frequently, and poor toddling

Abnormal gait

Knocking over objects, bumping into things, and destructiveness

Primary-school age

Difficulty with riding bikes, skipping, hopping, running, jumping, and doing somersaults

Awkward or abnormal gait

Older

Poor at sports, throwing, catching, kicking, and hitting a ball

Fine Motor Manifestations

Preschool age

Difficulty learning dressing skills (tying, fastening, zipping, and buttoning)

Difficulty learning feeding skills (handling knife, fork, or spoon)

Primary-school age

Difficulty assembling jigsaw pieces, using scissors, building with blocks, drawing, or tracing

Older

Difficulty with grooming (putting on makeup, blow-drying hair, and doing nails)

Messy or illegible writing

Difficulty using hand tools, sewing, and playing piano

DCD was included as a diagnosis in DSM-III-R and appears in essentially the same form in DSM-5-TR. The tenth edition of the *International Statistical Classification of Diseases and Related*

Health Problems (ICD-10) also includes the disorder, but the slightly more formalized definition requires an intelligence quotient of at least 70 and performance at least two standard deviations below the mean on a standardized test of motor coordination. In 1994, an international consensus meeting held in London, Ontario, agreed on the term DCD to describe children with a heterogeneous set of motor impairments that caused impairment in performing motor tasks compared to same-age peers. ICD-11 updated the disorder in by listing five essential criteria that more closely align with the DSM-5-TR criteria.

Although DSM-5-TR and ICD-10 and 11 view the disorder as a unitary undifferentiated syndrome, several investigators have suggested that there may actually be several distinct subtypes. Supporting that view is the individual variation in symptomatology, only some of which is clearly age-related. One recent attempt was to reclassify DCD proposed subtypes, such as ataxic syndrome (marked by unsteadiness and mild tremors), hypotonic syndrome (characterized by below-average resting muscle tone), tension syndrome (manifested by constant and excessively high levels of muscle tone), dyspraxic syndrome (identified by the inability to link a series of submovements necessary to execute smooth motor movements), manual–graphic syndromes (two separate manual syndromes, one marked by inadequate dexterity but adequate ability to reproduce written symbols and the other characterized by adequate dexterity but inability to reproduce written symbols accurately using fine motor movements), visual-perceptual clumsiness (ranging from ocular-motor problems involving inefficient movement of eye muscles to severe retinal deterioration), and mixed syndromes (a combination of symptoms already presented under the aegis of the previous six classifications). It is always important to keep in mind that significant ataxia, hypotonia, or any asymmetry between left- and right-side muscle function may be an indicator of a neurologic disorder and requires a neurologic assessment.

EPIDEMIOLOGY

The prevalence of DCD has been estimated to be approximately 5% to 6% among school-aged children. DCD has been noted in Europe, Asia, Africa, Australia, and North America. Clinical studies of children with DCD have historically found greater rates in boys than girls, of up to 7:1. More recent population studies have found less disparity, and report rates of approximately 2:1, male to female.

ETIOLOGY

A meta-analysis of performance deficits in DCD by Wilson and colleagues (2013) found that several clusters of deficits in learning motor skills emerged, suggesting that brain networks including parietocerebellar and cerebellar regions are involved. The clusters of motor skills dysfunction include “internal modeling of action” (predictive control of motor skills), rhythmic coordination and timing of motor movements, executive function, and dynamic control of posture and gait. The result of insufficient internal models, due to deficits in neural pathways in DCD leads to a lack of fluency and efficiency in coordinated movement. That is, the sequence of a complex motor movement in children with DCD is not properly or efficiently ordered, leading to awkward motions. Poor ability to coordinate a sequence of motor movements in DCD may be attributable to dysfunction in the corticocerebellar brain region. In terms of executive function deficits, impaired attention, working memory, and inhibition may contribute to poor action planning, and exacerbate overall poor motor coordination. The exact etiology of DCD is not yet clear; however, it is likely to include heritable factors, with potential prenatal and prenatal-developmental contributions. There is much heterogeneity in the expression of DCD. Motor control is dependent on numerous skills, including perception of objects in space, regulation of muscle activity, and balance. Children with DCD appear to be less proficient and less consistent in regulating muscle activity in heterogeneous ways. Some children with DCD are poor in manual skills, while exhibiting proficiency in balance, and for others, the opposite is true.

DCD and ADHD

Epidemiologic surveys have documented the comorbid occurrence of DCD in 30% to 50% of children diagnosed with ADHD. A study of children comorbid for ADHD and DCD in the Netherlands by Fliers et al., in 2007 confirmed previous research demonstrating a consistent increased risk of each of these disorders based on the presence of the other one. This study also investigated the association between the various types of motor coordination problems and inattentive versus hyperactive or impulsive subtypes of ADHD. In this study, data suggested that inattentive rather than hyperactive or impulsive symptoms were related to higher measures of motor coordination symptoms on the Developmental Coordination Disorder Questionnaire (DCD-Q) that was filled out by parents. This finding lends support for hypotheses that deficits in information processing are contributing problems underlying both ADHD and DCD. Although parents report that motor coordination problems often diminish with age, half of adolescents comorbid for ADHD and DCD continue to be impaired by coordination problems. One possible commonality between DCD and ADHD is a deficit in cerebellar activity. The coexistence of DCD and ADHD may reflect a shared heritable disturbance of the dopamine pathway. These two disorders may also share dysfunction in the basal ganglia and the prefrontal cortex.

DCD and Premature Birth

Evidence indicates biologic and cognitive-developmental correlates of DCD. The biologic-organic factors associated with the disorder include various birth and perinatal problems, such as low birth weight, prematurity, hypoxia, and neonatal malnutrition. A study by Marlow and colleagues investigated motor and “executive” cognitive function in 241 children who were born severely prematurely, at less than or equal to 25 complete weeks of gestation. These children were assessed at a median age of 6 years and compared with 160 classmates born at full term. Children underwent assessment of cognitive and neuromotor skills, including the Kaufman Assessment Battery for Children (K-ABC) and the NEPSY (a teacher-based assessment of academic achievement). Motor function was assessed by clinicians using the following items from the Movement Assessment Battery for Children (MABC): Heel-toe walking (15 steps), 1-leg balance (more than 20 seconds), and time to post 12 coins. Results from this study indicate that compared to classmates, children born severely prematurely and in the absence of cerebral palsy exhibited a high prevalence of impairment in gross motor function at early school age, in addition to impaired visual–spatial, perceptual-motor attention, and executive function. In each of the above impairments in motor skills or executive functions, at least half of the deficits were not accounted for by limitation of the overall cognitive score. Thus, motor and executive function disturbances in extremely prematurely born children are not due to compromised intellectual function but are more specifically associated with perceptual deficits. Children who were born extremely prematurely were observed to need more time for tasks compared to full-term classmates, and they were noted to have greater difficulty inhibiting associated movements and maintaining a secure postural basis during activities. As many as 7% of extremely prematurely born children were unable to balance on one leg for 20 seconds (compared to 1% of classmates). This study showed that extremely prematurely born children did not differ significantly from classmates on observed off-task motor behavior (17% vs. 25%), mirror movements (32% vs. 46%), and overflow movements (45% vs. 69%). Some investigators have postulated a continuum of reproductive casualty. There are also suggestions of incomplete cerebral dominance or lateralization, neurochemical abnormalities in the brain, and structural lesions in the parietal lobes.

DCD and Speech-Language Comorbidities

DCD frequently occurs concurrently with speech–language disorders and specific learning disorders, including reading disorders and dyslexia. A study showed that more than half of children with severe dyslexia exhibited motor coordination impairments severe enough to warrant intervention. Reading disorders, dyslexia, and speech and language disorders have been hypothesized to be associated with cerebellar involvement, as has DCD. One longitudinal study of children with language impairments revealed a continuing correlation between peg-moving performance and language performance. Another study found that fine motor skills, response speed, and upper limb speed were associated with language disturbances, whereas gross motor coordination and visual–motor control were not. Furthermore, evidence indicates that articulation problems are related to motor impairment, although the motor impairment is not necessarily dyspraxia.

DIAGNOSIS AND CLINICAL FEATURES

In 2012, The European Academy of Childhood Disability (EACD) published an interdisciplinary clinical guideline for the assessment, diagnosis, and treatment of children with DCD. These guidelines were subsequently revisited in 2019 to publish the international clinical practice recommendations on the definition, diagnosis, assessment, intervention, and psychosocial aspects of DCD. The essential feature of DCD is poor skill in daily motor activities for a given child's age and intellectual level. Impairments may be observed in gross motor activities, such as running, kicking, or catching a ball, as well as in fine motor coordination, resulting in poor ability to write letters neatly, to drink from a cup, or to use a knife and fork well. Children with DCD exhibit a heterogeneous pattern of impairments and thus function more competently in some motor task areas than others.

The current proposed criteria for diagnosis of DCD per the 2019 international clinical practice recommendations by EACD is similar to the DSM-5-TR diagnostic criteria for DCD (Table 41–2). Careful history-taking (preferably from parents, collateral sources other than parents, and the children themselves), problem-oriented clinical observation, and examination are essential to support the identification of the four diagnostic criteria. However, the recommended order of criteria application to arrive at the final accurate diagnosis of DCD involves first considering the age and medical history of the patient (criterion C), then ruling out other medical conditions (criterion D), analyzing the impact on activities and academic achievement (criterion B), and finally, quantification of motor impairment (criterion A). Due to the large variability of motor abilities in normal development, a formal diagnosis of DCD under the age of 5 years is only initiated by motor assessment in case of severe impairment and is usually confirmed by a second motor assessment at least 3 months apart.

Table 41–2.
DSM-5-TR Diagnostic Criteria for Developmental Coordination Disorder

A. The acquisition and execution of coordinated motor skills is substantially below that expected given the individual's chronological age and opportunity for skill learning and use. Difficulties are manifested as clumsiness (e.g., dropping or bumping into objects) as well as slowness and inaccuracy of performance of motor skills (e.g., catching an object, using scissors or cutlery, handwriting, riding a bike, or participating in sports).

B. The motor skills deficit in Criterion A significantly and persistently interferes with activities of daily living appropriate to chronological age (e.g., self-care and self-maintenance) and impacts academic/school productivity, prevocational and vocational activities, leisure, and play.

C. Onset of symptoms is in the early developmental period.

D. The motor skills deficits are not better explained by intellectual developmental disorder (intellectual disability) or visual impairment and are not attributable to a neurological condition affecting movement (e.g., cerebral palsy, muscular dystrophy, degenerative disorder).

Assessment Instruments for DCD

The Developmental Coordination Disorder Questionnaire. The DCD-Q is a 17-item parent questionnaire developed in Canada and validated to identify motor coordination problems in children aged 5–15 years by Wilson et al. (2000). For each item, parents rate the degree of coordination in their child compared to others of the same age on a 5-point scale. By adding the scores for each item, a total DCD-Q score can be calculated. In the study validating this instrument for young children, a score of less than or equal to 53 (15th percentile) was used as the criterion for DCD. The 17 items on the DCD-Q are:

1. Throw ball
2. Catch ball
3. Hit ball
4. Jump over
5. Run and stop
6. Plan activity
7. Writing speed
8. Writing legibly
9. Pencil pressure
10. Cutting
11. Team sports
12. Avoids sports
13. Rides bicycle
14. Learns skills
15. Clumsy
16. Awkward
17. Fatigues easily

The Movement Assessment Battery for Children. The MABC-second edition, was introduced by Barnett, Henderson, and Sugden in 2007 and provided an indication of gross and fine motor skills for children 4 years to 16 years of age. The MABC has two parts: a checklist and a performance test. On the MABC checklist, teachers rate the motor performance of children on 48 items reflecting everyday activities in the lives of children from 4 to 12 years. The checklist is divided into 4 sections, with 12 items in each section. On the performance test, there are four age-related item sets, each consisting of eight items that measure manual dexterity, ball skills, and static and dynamic balance. The checklist is a reliable instrument within sections and overall. Since the nature and severity of problems in DCD are very broad, an instrument meant to screen children with DCD must be able to measure a wide variety of motor skills.

Bruininks–Oseretsky Test of Motor Proficiency for Identifying Children with Motor Impairment. The Bruininks–Oseretsky Test of Motor Proficiency (BOTMP) assesses motor skills in children from 4½ to 14½ years old and provides a comprehensive index of motor proficiency as well as individual measures of gross and fine motor skills. In addition to the long form (LF), there is also a short form (SF), which consists of 14 items from the LF that have been validated. A recent study of the BOTMP in the assessment of preschoolers investigated the correlation between the LF and the SF of the instrument. Although the correlation between the two forms was high, short-form total scores were found to be significantly higher than long-form scores, identifying fewer children as having a motor impairment. Therefore, although the LF has been validated for young children, the SF is questionable in its ability to identify motor impairment in very young children.

Additional tests include the Frostig Movement Skills Test Battery, the Slosson Drawing Coordination Test, the Southern California Sensory Integration Test, and the Stott Test of Motor Impairment, which provide a comparative measure of a child’s abilities.

CLINICAL FEATURES OF DCD

Symptoms of DCD may be broken down into the following categories: dyspraxia, synkinesia, hypotonia, hypertonia, tremors, impersistence, and asymmetries. *Dyspraxia* describes a child's difficulty in exhibiting sequenced, coordinated motor movements when presented with an oral request. Movements identified as *synkinesia* are best described as unintentional muscle movements, also termed *motor overflow*. Mirror movements, such as finger twitching on the opposite hand when the child is asked to perform a finger opposition task or facial grimaces when the child is asked to make hand movements, are examples of synkinetic motor actions.

Two categories that describe muscle tone abnormalities are *hypotonia* and *hypertonia*. Hypotonia can be observed in all parts of the body and is characterized by a flaccid or sleepy quality in the child's facial expression and general muscle tone. Children with this condition may exhibit poor posture and obesity. Children with hypotonia often appear to be floppy and weak, but on actual muscle strength testing, they may have normal muscle strength. *Hypertonia* generally describes high levels of muscle tone in a child. For example, a child with hypertonic movement cannot finish drawing a line at a given point, instead overshooting the intended stopping point. Another example is a child who tends to throw a ball too hard and inaccurately at short distances.

The movement category of *tremors* is marked by irregular unsteadiness in motor movements observed in tasks requiring walking, drawing, or both. For example, legibly formed letters might reveal, on closer inspection, rapid tremors in the actual lines themselves. Unsteadiness might be exhibited in the child's gait as high-amplitude fluctuations in leg muscle movement.

The category of *impersistence* refers to the child's inability to sustain and maintain various body postures for reasonable periods of time. Asking a child to stick out their tongue is an example of a task used often to investigate impersistent motor movements. In this example, the clinician would keep track of how long the child could maintain this tongue position.

The final movement category, *asymmetries*, describes motor behaviors that affect only one side of the body. This category includes unusual flexions or muscle weakness, or both, on one side of the body or general muscle weakness in the limbs on one side.

These asymmetrical muscle movements can be observed by requiring a child to move laterally in a rapid manner (“like a basketball player on defense, not crossing your feet”). If the child executes the movement more fluidly on one side than the other, it might indicate an asymmetry. A child who is observed to have asymmetrical motor movements is likely to be referred for a magnetic resonance imaging (MRI) study to rule out an organic cause for this symptom. If the neurologic workup is negative, then this symptom may be considered part of a DCD.

Specific manifestations vary across individuals; thus, there is no typically clumsy child. In some instances, manifestations may be quite specific; one case report describes a child who could sew and do jigsaw puzzles without difficulty but could not write neatly.

The most common way to identify DCD is through the observation of delays in achieving motor milestones (e.g., sitting, standing, crawling, and walking). Gross motor coordination manifestations may be seen in difficulties with activities such as sitting, walking, running, balancing, throwing, and kicking. Fine motor coordination manifestations may be identified through difficulties in performing tasks, such as using utensils, tying laces, buttoning or zipping clothing, drawing, and, especially, printing or writing. During motor tasks, children with DCD may exhibit overflow movements in unsupported limbs, mirror movements, slight abnormalities of reflex, or poor ability to make movements smooth.

Some manifestations of DCD are age dependent. Young children show symptoms, such as delayed development, in early motor milestones and delayed acquisition of self-help skills, such as self-dressing (i.e., tying ties, fastening snaps, zipping zippers, buttoning, and unbuttoning) or self-feeding (handling a knife, fork, or spoon). Preschool-aged children may also have balance problems, awkward gait, and a history of frequently bumping into objects, falling down, and getting bruised. Problems with balance, hopping, jumping, catching and bouncing a ball, and tracing appear to be among the more common symptoms of school-aged children with DCD. A common sign of DCD among school-aged children is avoidance of sports activities because of poor performance or teasing by classmates.

In addition, children with DCD frequently have comorbid communication and learning difficulties. Among the more common of these difficulties are expressive language disorder, mixed receptive–expressive language disorder, phonologic disorder, reading disorder, disorder of written expression, and mathematics disorder.

Secondary complications for children with DCD often involve rejection from peers who are critical of their poor abilities in sports activities and other tasks. Over time, children who are chronically “picked last” for sports teams and who are unable to keep up physically with their peers may become demoralized or depressed. The DSM-5-TR diagnostic criteria for DCD are listed in Table 41–2. The ICD-10 and 11 diagnostic criteria for specific developmental disorder of motor function (ICD-10) and developmental motor coordination disorder (ICD-11) are presented in Table 41–3A and B.

Table 41–3A.
ICD-10 Diagnostic Criteria for Specific Developmental Disorder of Motor Function

A. The score on a standardized test of fine or gross motor coordination is at least two standard deviations below the level expected for the child’s chronological age.
B. The disturbance described in Criterion A significantly interferes with academic achievement or with activities of daily living.
C. There is no diagnosable neurological disorder.
D. Most commonly used exclusion clause. IQ is below 70 on an individually administered standardized test.

From World Health Organization. *The ICD-10 Classification of Mental and Behavioral Disorders: Diagnostic Criteria for Research*. 10th rev. World Health Organization; 1993, with permission. https://apps.who.int/iris/handle/10665/37108.

Differential Diagnosis

Informal observation by parents, teachers, and clinicians of gross motor coordination (e.g., hopping, jumping, and standing on one foot), fine motor coordination (e.g., finger tapping and shoelace tying), and hand–eye coordination (e.g., catching a ball and copying letters) is the most common initial screen for identification of coordination difficulties. However, given the vast normal variation in motor skills, it is often not easy to make a diagnosis of DCD. When coordination difficulties interfere with academic achievement or activities of daily living, however, formal testing and evaluation of these skills are recommended (Table 41–4).

Ruling Out Neurologic Disorders. Children with developmental motor disorders progress in gross and fine motor milestones, although at a slower rate than peers. They do not regress. Thus, a child who previously walked, ran, and climbed at age-appropriate levels but who no longer does these activities well should be evaluated for neurologic disorders. A child whose balance has deteriorated needs further testing to determine the cause of the change. Similarly, a child whose fine motor development was at the age expectation but who stopped using a hand, switched apparent hand dominance, or lost previous abilities should be assessed for other medical conditions. Even a child whose initial motor landmarks were delayed should be carefully investigated if they lose previously established abilities.

Table 41–3B.
ICD-11 Essential (required) Features for Developmental Motor Coordination Disorder

- Significant delay in the acquisition of gross or fine motor skills and impairment in the execution of coordinated motor skills manifesting as clumsiness, slowness, or inaccuracy of motor performance.
- Coordinated motor skills are markedly below that expected given the individual's chronological age and level of intellectual functioning.
- Onset of coordinated motor skill difficulties occurs during the developmental period and is typically apparent from early childhood.
- Coordinated motor skills difficulties cause significant and persistent limitations in functioning (e.g. in activities of daily living, school work, vocation and leisure activities).
- Difficulties with coordinated motor skills are not solely attributable to a Disease of the Nervous System, Disease of the Musculoskeletal System or Connective Tissue, sensory impairment, and not better explained by a Disorder of Intellectual Development.

Table 41–4.
Motor Signs and Symptoms Indicating Referral for Comprehensive Neurologic Evaluation

- Hypertonia
- Hypotonia
- Ataxia
- Tremor
- Chorea
- Weakness
- Asymmetry

Family history is important in consideration of neurodegenerative conditions such as spinocerebellar degeneration, Huntington disease, peripheral neuropathies, or other neuromuscular disorders. Further investigation should be pursued even if the positive family history is of onset in adulthood. Many dominantly inherited neurodegenerative conditions show “anticipation,” presenting in subsequent generations at earlier ages, even early childhood.

A physical examination, including a neurologic examination, should be performed. Skin stigmata, for example, may suggest a neurocutaneous syndrome (i.e., multiple café-au-lait spots, axillary or inguinal freckles suggesting neurofibromatosis type I (NF1); hypomelanotic macules, fibrous cephalic plaques, facial angiofibromas suggesting tuberous sclerosis). Excessive diffuse skin pigmentation, particularly in non–sun-exposed areas, is a clue to possible corticotropin excess, seen in boys in the early phases of adrenoleukodystrophy, at a time when the only other complaints may be loss of adept motor skills and behavior problems. Dysmorphic features, even subtle, may suggest an etiology. The presence of scoliosis, a dimple, bulge, or hair tuft over the spine, or limb asymmetries may suggest that the motor findings are due to a structural spinal cord abnormality. Examination of the ocular fundi is sometimes challenging in small children but is particularly important if loss of motor milestones is accompanied by other symptoms such as headache or vomiting.

Screening evaluation of cranial nerve function in young children is most easily assessed by observation of eye movements, facial movements, listening to the quality of speech, and watching the child swallow. For example, a child who cannot easily swallow water from an open cup or who coughs or gags when doing so may need to have a gag reflex formally tested. The extremities should be evaluated for muscle bulk, tone, and symmetry of length and girth. Asymmetric extremity size suggests either a structural brain or spinal cord lesion. In young children, strength is best assessed by observation of the child performing specific activities, such as rising from the floor, climbing onto a stool, reaching overhead for a toy, jumping, and hopping. Diffuse or symmetric muscle atrophy or weakness may suggest a neuromuscular disorder (i.e., muscular dystrophy, congenital myopathy, and neuropathy), malnutrition, or systemic illness. For example, boys with early manifestations of Duchenne muscular dystrophy may appear motor delayed and maladroit well before there are obvious complaints of weakness. Although testing of tendon reflexes may yield somewhat inconsistent results in young children, consistent asymmetries, the complete absence of reflexes, or frank hyperreflexia, clonus, or extensor plantar responses mandate further investigation. Gait should be observed in multiple ways: Watch the child walking, running, tandem walking, skipping, and walking on heels and toes. In addition to watching the gait pattern, the examiner should pay attention to posture and movement of the upper extremities as the child walks or runs. Abnormalities such as asymmetric arm swing or dystonic posturing of one or both hands are sometimes only appreciated with activity. Balance can be assessed both by watching the child perform ordinary activities, such as rising from the floor, walking, or turning, and by more structured tasks, such as standing on one foot. Frank ataxia, as opposed to immaturity and delay in acquiring skills, should mandate additional investigations. Many different genetic conditions present with truncal ataxia, with or without other deficits. The initial presentation may be relatively subtle. Fine motor abilities can be observed both directly (i.e., finger-to-thumb tap, thumb-to-sequential-finger-tap) and by watching the child during age-appropriate activities. For example, watch the child pick up a toy, color, write, use a handheld computer game or tablet-type computer, drink from a cup, or use a spoon. Look for asymmetries, dystonic posturing, or tremor. Look for tremor or dystonic posturing of the outstretched arms.

Poor motor coordination frequently coexists with learning disorders and disruptive behavior disorders, such as ADHD, particularly in children with high levels of impulsivity. A child may meet the criteria for DCD and ADHD. The tendency for children with DCD to be accident-prone, to fall down, to hurt themselves, and to break objects may, at times, be construed as destructiveness. In the school setting, a child’s motor difficulty with holding a pencil and writing legibly may result in great frustration for the child and the teacher. For children whose impaired writing ability and poor production are inadvertently interpreted as a lack of motivation, demoralization is common, and an evaluation for special educational services may be warranted. Children with DCD are at higher risk for poor social skills and are often victimized by bullies.

Jimmy was referred for evaluation to determine his need for adaptive physical education (PE), age 9 years of age. Jimmy was failing PE, was unable to run a mile, and he could not throw or catch the ball, and was generally slow motorically. His classmates laughed because he looked so “funny” while running, and he always seemed to be getting hit with the ball instead of catching it. Jimmy was always picked last for team sports games and was beginning to be bullied by his classmates for his poor physical skills. Jimmy already had an accommodation for more time on tests due to his previously diagnosed ADHD. He was being treated with Vyvanse, which was working well. A developmental history revealed that Jimmy was born prematurely at 31 weeks, and his motor milestones were all delayed, although speech milestones were right on time. Currently, Jimmy was unable to tie his shoes correctly, and he struggled to handwrite letters correctly, but his parents were hoping that he would outgrow those problems. Upon questioning Jimmy’s current motor skills, it became apparent that not only was he having coordination problems but that he was now being rejected by peers and had become quite socially isolated. At home, Jimmy’s parents had accepted the fact that he was just a clumsy boy and noted that Jimmy constantly spilled his drinks and was awkward when he used a fork. His food often fell off a fork or spoon before it reached his mouth, and he had great difficulty using a knife and a fork. A comprehensive assessment of fine and gross motor skills yielded the following results: Jimmy was able to hop, but he could not skip without briefly stopping after each step. He could stand with both feet together but could not stand on tiptoe. Jimmy held a ball bounced to him at chest level, and he could not catch a ball bounced to him on the ground from a distance of 15 ft. Jimmy’s agility and coordination were measured with the Bruininks–Oseretsky Test of Motor Proficiency (BOTMP), which revealed functioning levels commensurate with those of an average 7-year-old child.

Jimmy was referred to a neurologist for a comprehensive evaluation to rule out neurologic disorders. On neurologic examination, Jimmy was found to have no signs of a specific neurologic disorder. Neurologic examination was negative for conditions that could account for his poor motor skills. Based on the history and findings on the BOTMP, Jimmy was given a diagnosis of DCD. Jimmy's symptoms included gross and fine motor impairments, poor balance, and mild hypotonia. Based on an individualized educational plan (IEP) meeting with his school, it became evident that Jimmy required an adaptive PE program for DCD and had other specific learning disorders. In addition to his known ADHD, Jimmy was found to have a writing disability. A treatment plan was developed that included twice weekly with an occupational therapist who used perceptual-motor exercises to improve his fine motor skills, particularly targeting writing and the use of utensils. Jimmy was also enrolled in a treatment program using motor imagery training to improve clumsiness and was also referred to a social skills group to help him deal more effectively with his peers.

Jimmy was relieved to be receiving help, especially for his handwriting and PE class, which he had been close to failing. Over a period of 4 months of treatment, Jimmy showed some improvement in the legibility of his handwriting, although he remained a slow writer. He was responsive to the stimulant medication, and his academic achievement improved as his attention span increased. Jimmy was receiving more praise from his teachers than ever before, and his classmates were teasing him less. As he began to feel better about himself, he began to try to play sports informally with his peers, although not competitively. He was given a modified PE program in school, and he was not required to play on teams, but he practiced throwing and catching a ball and was allowed to walk his mile at a slower time. Jimmy continued to exhibit some impairment in fine motor skills over the year, and he was cooperative with the therapeutic interventions, showed some continual improvement, and demonstrated improved peer relationships.

COURSE AND PROGNOSIS

Children with DCD represent a heterogeneous group with a variety of impairments in gross and fine motor behaviors needed for everyday living as well as in static balance. The profile of specific deficits for a given child is individual and has been shown in recent studies to be modified positively by specific motor skills interventions. The outcome of motor coordination disorder is influenced by the severity of the impairment, the age of initiation and duration of therapeutic interventions, and the presence of comorbid disorders. A recent study of preschool children with DCD at 7 to 8 years of age revealed that those children who had significant impairment at 5 years of age continued to show impairment 1.5 years later. Longer-term studies have shown that motor coordination improves over the long term in at least 50% of children when they reach adolescence. A 2-year follow-up study of children of primary school age who had failed a motor test battery revealed motor performance that, although improved, was still inferior to that of controls. The children with motor impairments also showed poorer educational performance than controls.

A 10-year follow-up of clumsy children and their age-matched, sex-matched peers was done in children over a period of 8 to 9 years. When first identified, the clumsy children were approximately 6 years of age; at follow-up, they ranged from 15 to 17 years of age. Follow-up testing indicated that the clumsy children were still significantly below the controls in most motor skills (e.g., dexterity, ball skills, balance, cutting with scissors, catching, and walking backward) and in global ratings by physical education teachers. The clumsy adolescents showed higher rates of dysgraphesthesia, dysdiadochokinesia, and motor slowness. In addition, the educational achievements of the clumsy adolescents were significantly poorer, and they had significantly lower perceived social competence than their nonclumsy peers. This finding substantiates reports of continuing secondary problems, including peer problems, low self-esteem, and academic struggles in children and adolescents with significant coordination difficulties.

A long-term follow-up of children with DCD and those with ADHD and DCD at 22 years of age suggests that there are psychosocial ramifications into adulthood. Psychosocial adjustment difficulties present in young adults with only DCD and those who were comorbid for ADHD included unemployment, use of substances, continued difficulties with reading, and legal problems.

DCD tends to improve in most individuals over time, and those with more severe impairment at a younger age, as well as those comorbid for additional psychiatric disorders, have the poorest prognoses.

TREATMENT

Interventions for developmental motor coordination can be divided into three major categories: (1) *Task-oriented* approaches such as Neuromotor Task Training (NTT) and Cognitive Orientation to Occupational Performance (CO-OP); (2) *Process-oriented* approaches such as Sensory Integration (SI) and kinesthetic training; and (3) *traditional physical and occupational therapy* such as perceptual-motor training, and a therapist-guided parent or teacher intervention. A meta-analysis of interventions to treat DCD in children by Smits-Engelsman and colleagues (2013) found that the strongest evidence of effective treatment for DCD was for task-oriented approaches and traditional motor training therapies, with process-oriented therapy yielding only weak efficacy.

Task-Oriented Approaches

Task-oriented therapies focus on learning particular motor skills with a focus on the aspects of the movements that pose the greatest difficulties for the child. NTT is a hybrid of practicing specific problematic specific motor skills with the addition of cognitive behavioral strategies to increase motor planning, reduce anxiety, and increase the incentive for trying. CO-OP is another form of task-oriented therapy which directs a child to form a mental model of how a particular set of movements will be accomplished and then review with the therapist how well the mental image fits the actual motor task trials. CO-OP consists predominantly of cognitive behavioral problem-solving approaches and utilizes cognitive behavioral strategies proposed by Donald Meichenbaum.

Computer gaming with virtual physical motor tasks has been found to benefit children with DCD, often without explicit instructions or learning. A study of children with DCD playing a computer game designed in which children need to catch a ball virtually on the screen showed that they used visual cues to help them virtually catch the ball without even realizing it. These children were able to improve their computer scores implicitly by practicing the game and making use of a perceptual cue without having to be specifically instructed on how to improve. This has implications for treatment in that in addition to providing direct instruction to children with motor coordination problems, improvement can also occur with practice through environmental cues that are not necessarily identified.

A newer task-oriented strategy is Nintendo Wii Fit Training (Wii training). The Nintendo Wii is a gaming system that combines motion sensor technology in handheld controls, and a balance board provides both aspects of biofeedback and virtual reality to the player. In this way, an interactive video game can serve as a therapeutic tool for motor skills improvement.

A study of 56 children between 6 years and 10 years with DCD compared NTT (n = 37) to Wii training (n = 19) by Ferguson and colleagues. Children in the NTT group were provided two sessions per week (45 to 60 minutes) for 9 weeks in which they played games such as soccer, tag, and netball under the guidance of therapists who facilitated the learning of motor skills, provided positive feedback, and manipulated the environment when necessary. Children in the Wii group participated in 30 minutes of gaming three times a week for 6 weeks under the supervision and guidance of therapists who encouraged, praised, and motivated the children. Games included sports such as cycling, soccer, skateboarding, and skiing. Games required that the children shift their weight from side to side and jump over virtual objects, and some games required twisting of arm movements. The results found mean motor performance scores in both groups improved during the course of the study. The NTT group showed greater improvement in overall motor performance, functional strength, and cardiorespiratory fitness, while the Wii group showed significant improvement in anaerobic performance. Thus, this study suggests that both NTT and Wii training can provide valuable therapeutic gains.

Overall recommendations for first-line interventions for children with DCD include task-oriented therapies of various types. Younger children can benefit from NTT for problems such as handwriting, that is, writing letters, even before they learn to read. Older children and those with verbal skills may be able to benefit from CO-OP approaches that incorporate more verbal planning. Nintendo Wii and other gaming interventions can be beneficial for children with DCD of all ages.

Process-Oriented Approaches

There has been only a weak suggestion from studies that process-oriented approaches are effective therapies for DCD. However, they are often used in conjunction with other strategies. Process-oriented interventions aim to target neural structures, such as the cerebellum, for improving balance, or sensory processes, such as proprioception, in children with DCD. Interventions aim to enhance and remediate sensory input processing, for example, sensory integration therapy (SIT). SIT approach was introduced in the work of Ayres in the late 1970s, who focused remediation on enhancing sensory information processing in order to achieve more accurate motor execution. Sensory integration programs are often delivered as a related service to children with DCD under the direction of occupational therapists. These programs prescribe specific physical therapies that attempt to modify the motor and sensory functioning of these children. These therapies are based on the notion that sensory integration disorders interfere with body movements and body awareness. Activities are designed to target the tactile, vestibular, and proprioceptive systems. A sensory integration program that addresses disorders affecting the proprioceptive system (bumping into walls and inability to button, skip, or write) might involve using scooter boards to improve balance and body awareness. Multisensory modalities, including visual, auditory, and tactile materials, are utilized in this form of treatment. Motor imagery training for clumsiness in children has received attention recently based on results from controlled investigations of this modality compared to perceptual-motor interventions. One study used a successful motor imagery intervention through CD-ROM, which contained six main training components for children with coordination difficulties. The components included visual imagery exercises involving predictive timing, relaxation, and mental preparation, visual modeling of fundamental motor skills, mental rehearsal of skills from an external perspective, mental rehearsal of skills from an internal perspective, and overt practice. This model of treatment is based on the notion that deficits in a child's ability to internally represent the movement tasks contribute to poor motor coordination. The ability for visual imagery of objects is not typically impaired in children with DCD. The previously mentioned training exercises were designed to improve the timing and accuracy of a given child's ability to visualize motor tasks, as well as to reduce muscle tension while imagining completing the given motor task. Finally, the children were trained to mentally rehearse the task before actually practicing it.

Traditional Physical and Occupational Therapy

Traditional physical and occupational therapies target actual activities of daily function and seek to improve the execution of these motor behaviors. A variety of cognitive-motor approaches have been utilized to improve the planning and execution of motor skills. One cognitive-motor approach to improving functional skills by Sugden and Hendersen has been updated and labeled ecologic intervention, which places emphasis on the actual control of movement and is done in a real-life setting.

Traditional perceptual-motor training consists of a combination of gross motor, fine motor, and perceptual-motor activities related to a child's actual daily motor tasks, such as hopping, skipping, jumping, climbing and moving through hoops, climbing ladders, and jumping on a trampoline, to practice competency. Specific tasks addressing fine motor skills, for example, handwriting training, includes activities to improve the grip of a pencil, wrist rotation, and posture. The results of the previously mentioned study were extremely notable in that the mental imagery treatment was as efficacious as traditional perceptual-motor training exercises in improving a given child's coordination.

An example of functional skill intervention would be those that address impairment in handwriting. It is estimated that between 10% and 30% of children exhibit persistent impairment in handwriting, a skill that remains a critical means of communication even in the face of the pervasive use of computers. Handwriting impairment is associated with academic skills disorders. Handwriting treatment approaches may include perceptual-motor, visual–motor, motor control, individualized interventions or exercises, and supplementary handwriting instruction. Few controlled studies have examined which techniques are most efficacious, and a survey of 50 pediatric occupational therapists found that 90% of them advocated an eclectic approach to interventions for handwriting improvement. A study of school-based occupational therapy intervention for school-aged children with poor handwriting legibility showed efficacy in improved legibility of letters. Children with handwriting difficulties in this study received direct traditional perceptual instruction on writing letters for approximately 30 minutes per week for approximately 7 months. This consisted of a variety of handwriting interventions, such as using vibration or resistance to writing to increase appropriate grip and writing on a chalkboard or a vertical surface to increase arm strength and stability while writing. At the end of this period, children made significant gains in handwriting legibility compared to a control group that did not receive the intervention. Handwriting speed in the children who received the treatment increased from 32 to 37 letters per minute. Although this was a trend toward speed, this did not represent a statistically significant increase in speed. Some students in the treatment group wrote their letters with a greater degree of deliberate care, and although this increased legibility, it may have actually diminished their speed. Overall, the increase in legibility applied to letters more than numbers but did not significantly increase writing speed.

Communication

42.1 Language Disorder

Tuana Kant, M.Sc., Emiko Koyama, Ph.D., Mahliqa Ashraf, H.B.Sc., and James L. Kennedy, M.D., F.R.C.P.C., F.R.S.C.

Communication disorders are among the most common problems exhibited by young children. Nonetheless, communication disorders often go unrecognized, particularly when they are comorbid with other emotional or behavioral problems. Thus, child psychiatrists, psychologists, and other clinicians need to be alert to the potentially damaging impact of communication problems on a child's overall well-being. Proficiency in verbal communication is critical to success in virtually all human activities and is therefore a highly valued skill-set in society and evolution. Individuals suffering from communication disorders may be unable to competently participate in everyday interpersonal, learning, and occupational situations. Limited participation in such key life activities may further restrict growth in communication and related domains.

To develop effective communication, children must master (a) language, the conventional code used to express ideas about the world, and (b) speech, the complex and rapid motor movements that translate such ideas into spoken words. Children need to also learn how to use language and speech appropriately in a given social context. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and its text revision (DSM-5-TR) recognize five diagnostic categories for communication disorders. One category concerns a disorder in language (language disorder), two categories relate to disorders in speech (speech sound disorder and childhood-onset fluency disorder), one category is associated with language use (social [pragmatic] communication disorder), and the final category covers communication disorder not otherwise specified.

DEFINITION AND COMPARATIVE NOSOLOGY

Individuals with language disorders show persistent impairments in the expression and reception (production and comprehension) of language. These impairments will manifest across different modalities, including speaking, writing, and sign language. The expressive difficulties may include limitations in vocabulary range, sentence complexity, and coherence in discourse. These expressive problems, however, are of less overall concern than the receptive difficulties. Children with receptive problems may manifest deficits in basic auditory processing skills, such as auditory discrimination, detection of rapid sound changes, association of sounds and symbols, and memory for sound sequences. Additionally, they may be slow to learn definitions, especially those that are uncommon or abstract. They may not understand the questions or comments of others and may misinterpret complex directions and explanations. They may have difficulty following conversations or learning from lectures. Because of comprehension failures, individuals with language disorders may give illogic or inappropriate responses. Furthermore, their comprehension problems may go unrecognized and instead may be misattributed to inattention, stubbornness, or other psychological or behavioral problems. Because of these problems, individuals with a language disorder would often have limitations in academic achievement, occupational success, and other social participation.

The definition of language disorder in DSM-5-TR combines elements of both the expressive and mixed receptive-expressive language disorders of the revised fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) and the 11th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-11). Both the DSM-IV-TR and the ICD-11 conceptualized the expressive and receptive subtypes as being mutually exclusive language disorders characterized by significant language problems, despite normal levels of nonverbal intelligence. DSM-IV-TR, however, differentiated between the developmental and acquired subtypes, whereas the ICD-11 only recognizes the developmental type, and acquired language problems such as acquired aphasia with epilepsy are listed under separate categories.

EPIDEMIOLOGY

The prevalence estimates of language disorder differ from roughly 3% to 15%. Receptive problems are thought to be somewhat less common than expressive problems. The variation in prevalence estimates is most likely due to differences in language measures used to define the disorder, the age of the children surveyed, and the nature of the sample tested (community or clinic referred).

Language disorders are more common in boys than in girls. Various studies have yielded sex ratios as high as 5:1 and as low as roughly 2:1.

Familial aggregation is characteristic of language disorders. A variety of methods (aggregation, pedigree, twin, adoption, and linkage studies) have provided clear evidence of genetic influences on language disorder. Complementary work also points to environmental input as a key factor that likely contributes to familial aggregation.

Approximately 10% to 15% of children younger than 3 years of age show delayed onset and slow initial progress in language development. Because of the large range of normal variability in the language production skills of young children, it is not yet clear whether an initial delay consistently warrants a diagnosis of language disorder. The majority (50% to 80%) of these children eventually acquire language skills within the normal range, but some show persistent language difficulties into adulthood. Children who continue to exhibit language problems after age 4 are more likely to experience long-term language deficits which may persist into adulthood, although the specific language profiles may change over time.

ETIOLOGY

There are no known causes for language disorder. Various factors have been shown to correlate with language disorder, but none has yet been established as causal. Language disorder most likely has multiple determinants, including various biologic and environmental factors. Different factors or combinations may be implicated in some cases and not others, as suggested by the heterogeneity in the population. At least seven general types of possible causal factors have been investigated: (1) brain abnormalities, (2) genetic factors, (3) environmental influences, (4) neurodevelopmental immaturity, (5) general cognitive factors, (6) specific linguistic factors, and (7) auditory processes. Each of the proposed factors enjoys some empirical support, but none has gained widespread acceptance as a plausible account for all cases of language disorder. Moreover, the factors are not mutually exclusive and may interact in complex ways.

Structural or functional brain abnormalities can now be studied in a sophisticated fashion with advanced neuroimaging techniques. Such abnormalities have long been considered possible causation factors in language disorder, because (1) language characteristics of language disorder resemble those of acquired language disorders that result from known neurologic insults, and (2) children with language disorders show elevated rates of soft neurologic signs (e.g., mixed cerebral dominance, attention problems, or fine motor difficulties). Neuroimaging studies of children with language disorders have demonstrated structural and functional abnormalities, often in brain regions known to be crucial for language processing (e.g., left hemisphere or certain subcortical structures). Nonetheless, many questions remain. Both the language disorder phenotype and the techniques used to examine the brain abnormalities differ greatly among the studies, making it difficult to draw conclusions about how underlying brain abnormalities contribute to the phenotypic language disorder. Furthermore, because of the important role experience holds in brain development, it is not clear whether the observed structural abnormalities are a cause or consequence of a language disorder.

Genetic factors have now been clearly implicated in language disorder, but it is far less clear just what these factors are and how they operate pathologically. Loci on chromosomes 13, 16, and 19 have been tentatively linked to differing aspects of language disorder in several studies. Moreover, 22q11 deletion syndrome and sex chromosomal aneuploidy have also been associated with language disorders. Although these regions are unlikely to be the sole determinants of genetic influences on language, their investigation may yield important insights. For example, some recent linkage studies have suggested that chromosome 16q may be associated with phonologic short-term memory and chromosome 19q with expressive language. Work also continues to refine or broaden the language disorder phenotype to accurately identify possible subtypes and modes of transmission. An interesting possibility suggested by several lines of evidence is that autism and language disorder may share some relevant genetic characteristics. Genetic factors may also be important in understanding the origin of the brain abnormalities noted earlier. However, genetic assessments are not yet part of the initial diagnostic techniques for language disorders. With advancements in the field of genetics, further robustical research is needed to implement genetic etiologic analyses in clinical practice during the tests for children presenting with symptoms of language disorders.

Various environmental factors may also be critical, at least in some cases of language disorder. Children from families of low socioeconomic status (SES) are at elevated risk for language disorder. Low SES, in turn, correlates with other known risk factors, such as single-parent family status, large family size, lower parental education, pregnancy and birth complications, lack of appropriate learning materials in the home, abuse and neglect. Children from low SES families are also at risk for malnutrition, other health problems, increased exposure to known toxins (e.g., lead), and limited educational and social opportunities. The amount and quality of linguistic input available to children have also been shown to vary dramatically across families, with some children hearing as few as 700 utterances a day and others as many as 11,000! Furthermore, and not surprisingly, these variations in input were strongly related to language development as measured by standardized tests. In adverse conditions, supportive extended family and neighbors may act as protective factors assisting the children’s language development. Further work is needed to clarify whether or how various environmental and input factors may interact with one another and, perhaps, with biologic factors to cause language disorder.

Neurodevelopmental immaturity may also underlie language disorder. Proponents argue that language development of children with language disorder generally follows a normal sequence and course but at a slower rate; that is, it is delayed rather than deviant. Delayed maturation of neural structures or slow myelination of neural pathways might also account for associated characteristics that are common in children with language disorder, such as attention and motor problems and other behavioral difficulties. Furthermore, such neurodevelopmental immaturities may occur more often in boys than in girls. A related view is that children with language disorder simply have language skills that fall at the lower end of the normal distribution. When basic yet essential skill sets that allow humans to mingle or operate independently are compromised due to language disorders, the evolutionary advantages humans possess to communicate are decreased, as such, children presenting with a diagnosis would be recognized as disadvantaged.

A variety of general cognitive factors have also been proposed to account for language disorder. Speed of cognitive processing is one such factor. Children with language disorder typically perform slower than their peers without the disorder on a variety of linguistic (e.g., naming or grammatical judgments) and nonlinguistic (e.g., fine motor or visual-spatial) tasks. This slower processing speed might somehow interfere with language learning. Some studies, however, failed to show any significant correlations between processing speed and language achievement. Another potential factor is cognitive flexibility, where children with language disorder may show reduced flexibility in adapting thoughts and behaviors to novel environments. Children with language disorder also show impairments in feedback processing, thus may have reduced feedback-based learning, affecting their overall learning capabilities compared to their peers. Others propose that phonologic working memory, the immediate maintenance and manipulation of verbal information, is a key cognitive factor in language disorder. Children with language disorder show deficits in phonologic working memory, which have been linked to deficits in vocabulary learning and reading proficiency. However, strong causal inferences about the role of phonologic working memory are not yet possible based on the available correlational evidence. Overall, differences in cognitive functions are found in preschoolers with language disorder when compared to preschoolers without, where verbal functions are more varying in children with language disorder.

In contrast to the neurodevelopmental immaturities and general cognitive delay perspectives, that imply that children with language disorder experience an overall delay but nevertheless follow a typical course of language development, some researchers have argued that children with language disorders may show specific lingering deficits in certain aspects of language that a young child with otherwise matched language ability may not show. For example, children with language disorders have particular difficulty in learning certain grammatical features (e.g., verb tense markers or pronouns in English) to the extent that their use of these features is poorer than that of younger children at the same milestone of language development. Much-needed cross-linguistic work in languages with varied grammars is helping theorists hone in on the commonalities and differences in the grammatical features that pose particular problems for children with language disorders who are learning different languages. At this point, however, these linguistic theories are primarily descriptive rather than explanatory.

Auditory problems have also been investigated as possible causes of language disorders. One concern is otitis media, an inflammation of the middle ear that results from ear infections or allergies. Otitis media is often accompanied by mild hearing loss, which is usually temporary if the underlying infection is treated. Repeated episodes of otitis media and associated hearing loss are common in young children during the earliest stages of language development. Although otitis media alone is not sufficient to cause language disorder, it may contribute in combination with other risk factors. A second concern centers on the auditory perception of sounds. Many (but not all) children with language disorders have difficulty perceiving small sound differences and rapid auditory transitions, which are aspects of the acoustic signal thought to be important in understanding speech. It has proven difficult, however, to develop convincing theoretical and empirical links between auditory perceptual skills and the various language difficulties shown by children with language disorder.

DIAGNOSIS AND CLINICAL FEATURES

The hallmark of language disorder is impairment in receptive and expressive language development. The rate of language growth is slower in children with language disorder than children with typical language development. The receptive and expressive language characteristics of affected children may be largely similar to those of younger children who are acquiring language in a typical fashion. Certain language features, such as the grammatical marking of tense, aspect, number, gender, or case may be especially difficult for children with language disorders to acquire. They may have difficulty learning the correct use of auxiliary or modal verbs (e.g., is, were, could), plurals (e.g., cats, geese), verb tense endings (e.g., -ing, -s, -ed), and pronouns (e.g., he, she, they). Children with language disorder may also demonstrate spelling difficulties where they may have decreased sensitivity to silent letters and make errors or omit silent letters while they are spelling.

Comprehension often varies with the complexity of the language. For example, words for familiar, concrete objects, actions, or relations may be comprehended (e.g., *wagon*, *apple*, *walk*, *give*, *in*, *over*), but those with less familiar, abstract meanings may be unknown (e.g., *neuron*, *freedom*, *receive*, *pretend*, *between*, *when*). Similarly, sentences with simple grammatical forms may be understood (e.g., “The boy is smiling.” “The phone rang.”), whereas those with more complex structures may be misinterpreted (e.g., “The car that rammed the bus was towed to the garage.” “Before she finalized the arrangements, she consulted with her lawyer.”). Complex or lengthy instructions, questions, and explanations may not be comprehended. When children with language disorders misconstrue the language and intentions of others, they may inadvertently make inappropriate responses or comments during conversations. Their comprehension failures may also contribute to confusion or inaccuracy in telling stories, relating events, and giving explanations, problems that may be further exacerbated by their expressive language limitations. When their comprehension difficulties are not recognized, children with language disorders may be mistakenly thought to be inattentive, lazy, or uncooperative.

The specific manifestations of language disorder vary with age. Some children with language disorder eventually acquire language skills within the normal range, but the overall prognosis is poorer for children with severe receptive language problems than for children with just expressive language difficulties. The expressive and receptive features adversely affect personal interactions and academic achievement because the spoken language is poorly expressed and understood.

Amy was a sociable, active 5-year-old who was diagnosed with a language disorder. She often played with Lisa, her kindergarten classmate. During pretend play one day, each girl told the story of Little Red Riding Hood to her doll. Lisa's story began: "Little Red Riding Hood was taking a basket of food to her grandmother who was sick. A bad wolf stopped Red Riding Hood in the forest. He tried to get the basket away from her, but she wouldn't give it to him."

By contrast, Amy's story illustrated her marked difficulties in verbal expression: "Riding Hood going to grandma house. Her taking food. Bad wolf in a bed. Riding Hood say, what big ears, grandma? Hear you, dear. What big eyes, grandma? See you, dear. What big mouth, grandma?

Eat you all up!"

Amy's story contained many features characteristic of children with language disorders at her age, including short, incomplete sentences, simple sentence structures, omission of grammatical function words (e.g., is and the), and inflectional endings (e.g., possessive -'s and present tense verb -s), problems in question formation, and incorrect use of pronouns (e.g., her for she).

Nevertheless, Amy performed as well as Lisa did in understanding the details and plot of the Riding Hood tale, as long as she was tested with methods that did not involve verbal responding. Amy also demonstrated adequate comprehension skills in her kindergarten classroom, where she readily followed the teacher's complex, multistep verbal instructions (e.g., "After you write your name in the top left corner of your paper, get your crayons and scissors, put your library books under your chair, and line up at the back of the room.").

Julio was a quiet, sullen 8-year-old whose language problems were no longer obvious in casual, social conversations. His speech now rarely contained the incomplete sentences and grammatical errors that were so evident when he was younger. His expressive problems, however, still surfaced in tasks involving elaborate or abstract uses of language, like those required in much of his third-grade academic work. An example was Julio's explanation of the outcome of a recent science experiment: "The teacher had stuff in some jars. He poured it, and it got pink. The other thing made it white." Although each sentence was grammatical, his explanation as a whole was difficult to follow because key ideas and details were omitted or poorly explained. Julio also showed problems in word finding, that is, in using specific words for the concepts and actions, he was describing. Instead, he relied on vague and nonspecific terms, such as thing, stuff, and got.

In early elementary grades, Julio had kept pace with his classmates in reading, writing, and other academic skills. By third grade, however, the increasing demands for written work began to negatively affect his overall academic standing. His written work was characterized by problems similar to those noted in his oral expression, such as poor organization and lack of specificity. Classmates also began to tease him about his difficulties, and he reacted quite aggressively, sometimes to the point of fighting. Nonetheless, Julio continued to show relatively good comprehension of spoken language, including classroom lectures concerning abstract concepts. He also comprehended sentences that were grammatically and conceptually complex (e.g., "The car the truck hit had hubcaps that were stolen. Had it been possible, she would have notified us by mail or by phone.").

Susan was a pleasant 2-year-old who did not yet use any spoken words. She made her needs known with vocalizations and simple gestures (e.g., showing or pointing) like those typically used by younger children. She seemed to understand the names of a few familiar people and objects (e.g., *mommy*, *daddy*, *cat*, *bottle*, and *cookie*). However, compared to other children her age, she had a small comprehension vocabulary and showed limited understanding of simple verbal directions (e.g., “Get your doll.” “Close your eyes.”). Nonetheless, her hearing was normal, and her motor and play skills were developing as expected for her age. She showed interest in her environment and in the activities of the other children at her daycare.

Min was a shy, reserved 5-year-old who grew up in a bilingual home. Min's parents and older siblings spoke English and Cantonese proficiently. Her grandparents, who lived in the same house, spoke only Cantonese. Min began to understand and speak both languages much later than her older siblings had. Throughout her preschool years, Min continued to develop slowly in comprehension and production. At the start of kindergarten, Min understood fewer English words for objects, actions, and relations than her classmates did. She showed difficulties in following classroom instructions, particularly those that involved words for concepts of time (e.g., *tomorrow*, *before*, or *day*) and space (e.g., *behind*, *next to*, or *under*). It was also hard for Min to match one of several pictures to a syntactically complex sentence that she had heard (e.g., "It was not the train she was waiting for." "Because he had already completed his work, he was not kept after school."). Min occasionally tried to speak with other children. However, these conversations usually broke down because she misinterpreted what others said or could not express her own thoughts clearly. Consequently, her classmates generally ignored her, preferring instead to play with more verbally competent peers. Min's infrequent interactions further limited her opportunities to learn and practice her already weak language skills. Min also showed limited receptive and expressive skills in Cantonese, as revealed by an assessment conducted with the assistance of a Cantonese interpreter. Nonetheless, her nonverbal cognitive and motor skills were within the normal range for her age. She showed no difficulties in solving spatial, numerical, conceptual, or analogic problems, provided they were presented nonverbally.

Fred received a diagnosis of language disorder when he was a preschooler. By 8 years of age, he had also received the comorbid diagnoses of specific learning disorder and attention-deficit/hyperactivity disorder (ADHD). This combination of language, learning, and attention problems made it virtually impossible for Fred to succeed in school. His comprehension and attention difficulties limited his ability to understand and learn important information from classroom instructions, discussions, and lectures. Because the unlearned information was critical to the understanding of future academic lessons, Fred fell further behind his classmates. He was also disadvantaged by the fact that he could read only a few familiar words. This meant that he could not learn other academic information that his classmates acquired by reading textbooks, library books, newspapers, and other written materials. His poor reading ability also limited his opportunities to learn the new vocabulary, complex sentence forms, and sophisticated ideas that other children absorbed from reading. Despite his academic problems, however, Fred continued to show nonverbal intellectual skills within the low normal range, although his scores were somewhat lower than those he had earned as a preschooler.

The disorders of speech, learning, and development may co-occur with language disorder. The two most frequently co-occurring disorders are speech sound disorder and specific learning disorder. Speech sound disorder, which is characterized by difficulty in the correct production of speech sounds, occurs in roughly 40% to 60% of preschoolers with language disorder. Specific learning disorder, especially difficulties in reading, occurs in approximately 50% to 90% of school-aged children with language disorder and most frequently for children with receptive language problems. Difficulties in learning to read may be apparent early or may not surface until later in the learning process when knowledge of sophisticated vocabulary and sentence structures is required to support reading comprehension. Because of this high comorbidity between language disorders and reading problems, some researchers have theorized that language impairment and reading difficulties may be different manifestations of the same underlying problems that manifest themselves at different ages. Following this idea, they suggest that in the evaluation of spelling difficulties in language disorders, phonologic representations, morphologic awareness, and reading skills should all be assessed. Genetic studies also suggest that families with a known risk of language disorders also tend to be at higher risk for reading problems and vice versa. However, other researchers suggest that reading and language problems should be considered separate disorders, as children with language problems manifest problems that go beyond phonologic awareness and include syntax and semantics. Future studies in molecular genetics may help clarify this debate. Similarly, children with language disorder have an increased risk of exhibiting mathematics disorder. A few children with language disorders also experience childhood-onset fluency disorder (stuttering) and developmental co-ordination disorder.

The risk for concomitant psychiatric disorders is high for children with language disorder, especially when receptive language is impaired. Estimates vary, but comorbid psychiatric disorders may affect as much as 70% of school-aged children with language disorder who have severe receptive language problems. The most common comorbid condition is ADHD, occurring in 30% to 60% of cases. Internalizing disorders are also noted but not as often as ADHD. Genetic studies show that the co-occurrence of internalizing disorders with language disorder may be due to common genetic influences. Therefore, children with language disorder may be at a higher risk for internalizing disorders if they already have a genetic predisposition for internalizing problems. Boys are at particular risk for externalizing disorders, where genetic influences may also affect this co-occurrence. Behavior difficulties tend to occur most frequently in children who have concomitant language and reading problems. Girls with language disorders may be withdrawn and quiet, making the detection of language disorders more difficult.

Most children with language disorder do not show frank neurologic symptoms (e.g., tremor, paralysis, or seizures). As a group, however, children with language disorders show elevated rates of mild-to-moderate abnormalities (e.g., in reflexes or fine motor function) on careful neurologic examination. They are also more likely than typically developing children to show mild-to-moderate abnormalities in measures of brain function or structure, such as electroencephalographic (EEG) readings, magnetic resonance imaging (MRI) and functional MRI (fMRI) scans, or diffusion tensor imaging (DTI)-derived fractional anisotropy (FA).

Furthermore, the number of abnormal neurologic signs may be associated with the severity of language difficulties.

With advancing technology, new techniques are being tested to improve the detection and intervention of language disorders. Language disorders may go undiagnosed without proper detection. Automatic speech recognition was tested and showed better accuracy than manual transcribers, providing a promising technique to transcribe sentences and improve the detection of language disorders in school-aged children. Moreover, automated computationally driven techniques in scoring the results from language tasks for children have also been shown to be an effective and accurate method to be used instead of manual entry, which may increase the efficacy and objectivity of measurements. Eye tracking has also shown promising results in detecting early steps of language disorders, where children with language disorder may show slower and atypical verb-based prediction behavior. Overall, researchers suggest that instead of focusing on linguistic measures, analyses of a combination of both linguistic and nonlinguistic features may provide a more accurate detection of a language disorder.

PATHOLOGY AND LABORATORY EXAMINATION

There are no laboratory tests that can provide a diagnosis of language disorder. Neuroimaging techniques, such as MRI and fMRI, sometimes reveal structural or functional brain abnormalities associated with language disorder. There are also new techniques being tested with EEG, where machine learning is being tested to classify infants' neural responses to rhythms in order to identify high-risk children for language disorders. However, such abnormalities have neither been found in all cases nor have their possible etiologic or diagnostic values been determined.

DIFFERENTIAL DIAGNOSIS

Standardized evaluations of expressive and receptive language and nonverbal intellectual functioning are the key elements for differential diagnosis of language disorder. Receptive language testing is particularly important because comprehension deficits may be less obvious than expressive difficulties. Receptive and expressive language performance must fall substantially below the range of normal language performance expected for a child’s age. In addition, the severity of the receptive and expressive language problems must hinder academic performance or social communication. Speech-language pathologists often use observational techniques and analyses of spontaneous language to assess the functional impact of language difficulties and to complement information obtained from standardized language tests. A thorough functional assessment of language abilities may also be substituted when appropriate standardized tests are not available (e.g., if a child speaks a language for which tests have not yet been developed).

A significant discrepancy between receptive language and nonverbal abilities precludes the alternative diagnoses of selective mutism and intellectual disabilities. In selective mutism, receptive language and nonverbal performances usually are similar in level and markedly higher than expressive language skills. In intellectual disabilities, performance is impaired substantially in all three areas of receptive language, expressive language, and nonverbal abilities relative to age-level expectations.

Deficits in receptive language may also be evident in cases of hearing impairment, environmental deprivation, or autism spectrum disorder. A hearing test should be part of the assessment of all cases of suspected language disorder. Collection of a careful history can usually identify severe environmental deprivation. Observations of disturbed social interaction, limited communicative intent, and unusual repetitive behaviors suggest autism spectrum disorder. A concurrent diagnosis of language disorder may be made when receptive and expressive language deficits exceed those expected for the degree of intellectual disabilities, hearing impairment, or environmental deprivation.

Differential diagnosis requires attention to other comorbidity issues. Speech sound disorder is a possible comorbid diagnosis when difficulties in speech sound production accompany language disorder. School-aged children identified with either language or specific learning disorder should be screened for difficulties in the other area because the two disorders frequently co-occur. Similarly, children with psychiatric diagnoses, particularly ADHD, should be screened for language disorder because it is known that a high proportion of children referred for psychiatric assessment shows previously undetected comorbid language disorders. Moreover, children with receptive and expressive language deficits may show signs of reduced autonomy in their play behaviors, as well as reduced eye contact with their parents, which can be monitored even in their prelinguistic skills. Furthermore, sometimes a child shows expressive language that is so difficult to follow and so disorganized that the practitioner questions whether it should be considered disordered thinking as a symptom of schizophrenia.

Illustrative of this concern is the case study presented here with a brief excerpt from a conversation with Max, a highly anxious 9-year-old with language disorder who had just visited the dentist. The stream of language in this case study raises serious concerns about a possible diagnosis of schizophrenia. However, a child with language disorder may produce language this disorganized, especially in situations of heightened anxiety. Diagnosis can usually be clarified by reassessment when the child is less anxious and by careful attention to the presence or absence of comorbid symptoms.

What do you suppose you'd like to do today?

Taking a dentist appointment …

[You're taking a dentist appointment.]

Yeah, he has a little cavity …

[He has a little cavity.]

…and I'm going to take it from him cause he's stuck there he sure doesn't like it but he knows there is too far (mumbled)…

…too far and so he was losing a lot of hair so he needs a new way…sounds like he's bald…so he has everything (mumbling) a guy who's not recep…teaching he will have to it's important like he will or he won't.

Acquired language problems may result from a variety of neurologic insults, including (1) cerebral vascular accidents, such as strokes; (2) infections, such as encephalitis, meningitis, or Zika virus; (3) severe respiratory problems that result in intraventricular hemorrhage or anoxia; (4) near drownings; (5) closed head injuries from falls, motor vehicle accidents, or other blows to the head; (6) open head injuries, such as those from gunshot wounds; (7) toxins, such as lead or household poisons; (8) damage from tumors or radiation treatment; or (9) seizure activity. Landau–Kleffner syndrome (acquired aphasia with epilepsy) is a rare condition marked by an abrupt loss of language skills, which is often associated with the onset of seizures or abnormal EEG activity.

Acquired language problems vary considerably in their language symptoms as a function of the nature and severity of the underlying neurologic condition. Acquired disorders also show distinctive language characteristics as well as some features shared with language disorder. For example, closed head injury, which often occurs in motor vehicle accidents or falls, typically are sparing of basic skills in vocabulary and grammar (after initial recovery stages), whereas more complex skills, particularly in discourse, remain markedly impaired. Comprehension for lengthy or complex discourse may be limited. Likewise, expression in discourse may be disrupted by disorganized, tangential, inappropriate, and illogic comments, even if basic vocabulary and sentence structures are used correctly. Communication effectiveness may be further hindered by accompanying deficits in memory, attention, affect, behavior, and motor skills. In return, these problems and deficits in language skills acquired as a result of brain trauma may create additional obstacles in the rehabilitation process for the injury itself.

Landau–Kleffner syndrome also shows a unique pattern. Children with Landau–Kleffner syndrome seem to be developing normally until around the ages of 3 to 7 years, when they start to have trouble with expressive and receptive language for no apparent reason. The decline in language ability may be sudden or gradual. Hearing loss is usually suspected by parents; however, laboratory tests disconfirm this suspicion. In about 80% of children with Landau–Kleffner syndrome, one or more episodes of epileptic seizures occur, typically during sleep. Behavioral problems such as hyperactivity, aggressiveness, or depression may co-occur.

Elliott, 4 years of age, was a cheerful, talkative preschooler who suddenly experienced a series of seizures for no apparent reason. His language skills, which had been excellent, simultaneously showed a precipitous decline. He no longer understood words, commands, and sentences that had posed no difficulty for him before the seizures. He also lost his expressive skills and began using shorter, less sophisticated sentences, which became increasingly incoherent as he omitted or misused important words. He also developed significant memory and attention problems. Nonetheless, he continued to show nonverbal intellectual skills that were grossly within the normal range. Although Elliott's seizures were eventually controlled with medication, he experienced persistent problems in comprehension and production of language, which never fully resolved.

Course and prognosis are also variable for children with acquired language problems. Some spontaneous recovery generally occurs rapidly within days or weeks of the neurologic insult, but additional improvements may show a protracted course over months or even years. Approximately two-thirds of children with acquired disorders eventually recover language functioning that is broadly within the normal range, although subtle deficits may persist. Those who do not attain normal language functioning show persistent language and cognitive deficits of varying severity. Prognosis depends on many factors, including the severity, extent, and location of brain damage, the specific etiology, the age of onset, the extent of preinjury language development, and the existence of other preinjury disorders.

Language disorders also occur in children from diverse linguistic and cultural backgrounds. A difficult diagnostic challenge is to differentiate language errors that are a normal part of acquiring a new language from those that are indicative of a disorder. A valid assessment usually requires the co-operation of a well-trained informant from the same cultural and linguistic background as the child. The informant assists in collecting and interpreting history information, assessing the child's skills in the other language, and discussing assessment results and recommendations with the family.

COURSE AND PROGNOSIS

Language disorder is characterized by considerable variability in severity, course, and outcome. Individuals who have mild-to-moderate language disorders are less likely to suffer from significant long-term mental health problems than individuals who have severe language disorders. Youngsters with early receptive language delays show higher rates of persisting disorder and less favorable long-term outcomes than those with early expressive-only delays. Some, however, do eventually attain language functioning within the normal range. Better outcomes are generally associated with higher levels of early gestural communication, receptive language, and nonverbal intelligence.

Children with persistent language disorders continue to develop language comprehension and production skills during the preschool and school-aged years. However, the rate of development may be quite slow, causing them to fall further behind peers who are developing language at a normal rate. Overall, the communicative prognosis for children with persistent language disorders continues to be poorer than for those with expressive-only disorders.

Children with language disorders are also at risk for academic problems once they enter school. A negative spiral of poor academic performance, low self-esteem, reduced motivation, and social isolation may stem from the language comprehension difficulties, particularly when they are coupled with attention, reading, or mathematics problems. Fortunately, some progress has been made in using performance on early language-related tasks to predict which kindergarten children may be at risk for later reading difficulties. Moreover, interventions to improve phonologic awareness, a key skill for early reading, have proven successful with children with language disorders, at least in the short term.

Many adolescents and young adults with a history of language disorder continue to show problems in communicative effectiveness, academic performance, and social functioning. These problems may limit vocational choices and social participation. Individuals with language disorder are also at heightened risk of being bullied or victimized in general, including sexual assault or abuse for girls and women. Serious psychiatric problems, such as social anxiety disorder or antisocial personality disorder, may also develop in some individuals. Even though the symptoms of language disorders may improve through development in most children, the internalizing or externalizing behavior problems that co-occur with language disorders may not get better with this improvement.

The societal consequences are significant, as evidenced by the high rate of language difficulties in adults who live in poverty, commit crimes, incur psychiatric illnesses, and achieve limited literacy.

TREATMENT

Experts disagree about the timing of intervention for language disorder. Some advocate a wait-and-see attitude for young children with early expressive delays (late talkers) because most acquire normal language functioning during the preschool years. They argue that intervention should be provided only to those with persistent expressive delays at 4 or 5 years of age. Others suggest that early intervention might prevent or minimize later language, academic, and behavioral difficulties. Unfortunately, few relevant data are available on the efficacy of early- versus late-language intervention.

Direct and mediated interventions have been shown to promote short-term language growth in children with language disorders. In direct interventions, the primary intervention agent is a professional (usually a speech-language pathologist) who works directly with the child to improve language functioning. In mediated interventions, the primary intervention agents are parents, teachers, or paraprofessionals, who have been taught by the speech-language professional to deliver the intervention to the child. Mediators are encouraged to incorporate language facilitation techniques into daily activities and routines, thereby providing regular, naturalistic opportunities for children to use newly learned language features.

Further research on treatment efficacy is needed to address important outstanding issues. For example, studies are required to assess (1) the ways in which interventions might be tailored to address the specific language needs of individual children, (2) the long-term merits of early intervention for children with expressive delays, (3) the extent to which the benefits of intervention achieved in laboratory studies can also be demonstrated in routine community-based interventions, and (4) what the potential harms of early screening or intervention for language delays may be, including the risk involved in false-positive and false-negative results, labeling, parent and child anxiety, and unnecessary evaluation and intervention. One recent study of routine early interventions suggests that systematic efforts may be required to improve their effectiveness.

Children with language disorders are generally recommended for intervention to address their receptive and expressive language needs. Various language intervention techniques and programs have been developed, but some have not been rigorously evaluated to demonstrate their efficacy. The available efficacy literature, however, suggests that language intervention can foster short-term progress toward specific communicative goals, a conclusion that extends to various intervention techniques and programs. With advancements in technology, different technologic intervention techniques have been tested to improve the treatment outcome. For children with co-occurring speech sound and language disorders, electropalatography (EPG), a technique that monitors contacts between the tongue and hard palate, has been shown to be effective in improving regular speech and language therapy outcomes. Another method that is being developed with advancing technology is a speech and language guidance program as an application for smartphones and tablets, where parents and children have an opportunity to benefit from language therapy remotely with lower costs. Unfortunately, there has been limited study thus far on the possible long-term benefits of language intervention in limiting or reversing the negative impacts of language disorder on linguistic, academic, and psychosocial outcomes.

Interventionists have, however, begun to focus on long-term, broad-based outcomes. Preschoolers with language disorders are receiving interventions designed to promote not only oral language outcomes but also social communication and early literacy skills. Kindergartners with language disorders are being taught certain key prereading skills, which may prevent the early reading failure that is linked to subsequent academic and psychosocial problems. More attention is being given to enabling peers, parents, and teachers to learn methods for fostering frequent, natural, and optimal communicative interactions with children who have language disorders. In schools, there are efforts to co-ordinate the various types of interventions that may be required by a child with a language disorder (e.g., language intervention, special reading help, special education support, or behavioral interventions), as well as to train childcare professionals in delivering group interventions which have been effective in increasing children’s phonologic production skills. Even though the parameters for effective dose and intensity of interventions in clinical practice are not yet clearly defined, recent research showed that twice a week may be a more effective method than once a week. Despite some initial promising results from these efforts, much remains to be learned concerning optimal goals, techniques, and programs for language intervention.

Language disorders may also necessitate modifications to other interventions that rely heavily on language as a medium (e.g., psychotherapy or cognitive behavioral modification). Comprehension can be facilitated by simplification of vocabulary, sentence structure, questions, and verbal instructions and by repetition of verbal information as required. Compensation for expressive difficulties can be achieved by using nonverbal response modes to supplement verbal responses. Ambiguous or unclear responses should also be clarified. Assessment procedures that depend heavily on language (e.g., projective tests or diagnostic interviews) may require similar modifications.

Overall, people with language disorders are underserved. The discovery and application of better detection and intervention techniques are necessary to provide better care for this population. Raising awareness, providing detection tests in early stages and in-school settings, and better communication with parents and teachers are some ways that can enhance our current level of knowledge and experience with language disorders.

ACKNOWLEDGMENTS

This chapter was written in memory of the late Dr. Joseph H. Beitchman, who continues to inspire us with his dedication, devotion, and extensive research work in childhood language disorders.

▲ 42.2 Social (Pragmatic) Communication Disorder

MIRELLE KASS, B.A., YOUNG SHIN KIM, M.D., M.S., M.P.H., PH.D., AND BENNETT L. LEVENTHAL, M.D.

Social (pragmatic) communication disorder (SCD) is a persistent disruption in the communication of social concepts, skills, and intentions. While social communication deficits coexist as a component of multiple disorders, for individuals with SCD, these problems stand alone.

Social pragmatics is derived from the concept of pragmatic language. Language is the full spectrum of expressive and receptive communicative behaviors, including speech, gesture, and other skills. Pragmatics encompasses those behaviors that contribute to implication, relevance, and effectiveness of any form of an individual's communication. In this framework, for effective communication, an individual must follow pragmatic language rules to create and transmit any given message. Similarly, individuals must understand pragmatic rules when attempting to interpret receptive communication.

Language pragmatics relate to how context contributes to understanding and meaning in communications, with each component of communication having its own structure and rules. When speech is used, the rules apply to what is being said and how it is being said. The “what” refers to the choice of words, sentence structure, and connections between different elements of content, such as conjunctions and dependent clauses, as well as the use of different types of sentences (statements, questions, etc.). The “how” of speech applies to the rate, rhythm, prosody, volume, tone, and other characteristics of speech production. Pragmatic rules also apply to nonverbal communication, including gesture, body posture, reciprocity, and facial expression. When the pragmatic rules can be correctly and flexibly applied in context, expressive and receptive language can be effective. When they cannot be so applied, individuals have broad difficulties in social intercourse leading to significant problems in adaptation.

SCD is a diagnostic category first introduced in DSM-5. The main characteristic of SCD is the persistent deficit in the social use of expressive and receptive, nonverbal and verbal communication, as well as difficulty using the linguistic context to make inferences and to resolve ambiguities. Symptoms of SCD include deficits in the understanding and the application of social and language rules for verbal and nonverbal communication. Individuals with SCD have difficulty adapting language to the needs of the listener or situation. Similarly, those with SCD have difficulty following the rules of conversations (such as turn taking), storytelling, humor, sarcasm, and other nuanced speech. As a result, individuals with SCD have difficulty communicating and understanding ambiguous and nonliteral language, as well as integrating linguistic context and prior social knowledge.

The elements of SCD overlap with the “A” criterion of DSM-5-TR autism spectrum disorder (ASD). However, SCD is distinct from ASD due to the absence of the DSM-5-TR ASD “B” criterion, “restricted, repetitive patterns of behavior, interests, or activities….” Although SCD can co-occur with other communication disorders, such as language disorder, the social communication and pragmatic deficits for SCD must exceed what would be expected from structural language deficits alone. The diagnosis of SCD cannot be made along with the diagnosis of ASD.

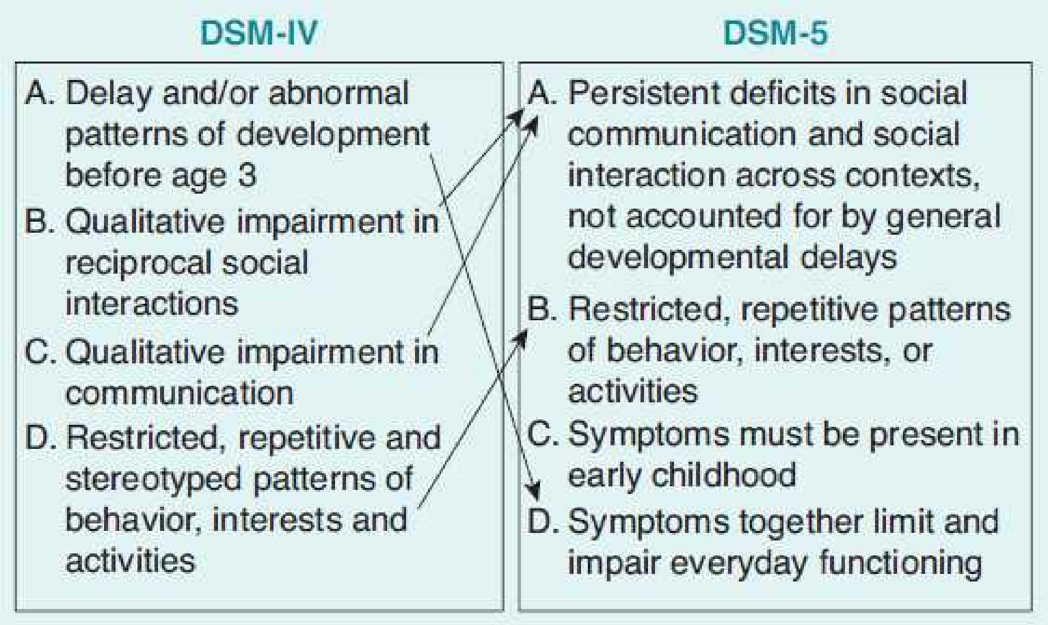
HISTORY

While social and language pragmatics have long been a clinical concern for many disorders, SCD was not considered a diagnostic category until the creation of DSM-5. Social communication and pragmatic deficits have been documented in the education and speech and language literature for decades, if not longer. Much of the concern about SCD, and other language disorders, focused on children although it is apparent that SCD and other developmental language disorders (DLDs) persist into adulthood.

Previously, semantic–pragmatic deficits characterized children demonstrating problems with verbosity, word finding, word choice, and poor topic maintenance. A similar term introduced in the late 1980s was “semantic–pragmatic disorder,” which was thought to occupy the diagnostic space between ASD and specific language impairment. Both terms reflect the idea that semantic (i.e., the meaning of an expression) and pragmatic (i.e., the use of language in context) difficulties tend to co-occur. In the 1990s, research found that semantic deficits did not necessarily co-occur with pragmatic deficits, and that semantic abilities did not reliably differentiate between typically developing and clinical groups. As a result, the term pragmatic language impairment was coined and appears commonly in the speech and language literature.

While there was much research and clinical progress in understanding etiologic substrates and clinical presentation of autism, as a result of unifying diagnostic criteria between DSM-IV and ICD-10, there was still substantial difficulty distinguishing the subcategories in DSM-IV pervasive developmental disorder (PDD). Research found no etiologic distinctions and a lack of diagnostic reliability with these criteria. In part, this was due to Asperger syndrome becoming a preferred diagnosis for many families because it was associated with much less stigma than the DSM-IV diagnosis of autistic disorder—even today, some still falsely “blame” parenting failure as a cause of autism.

The addition of SCD to DSM-5 is closely associated with the changes made to the diagnostic criteria concerning ASD. In DSM-IV-TR, PDDs included autistic disorder, Asperger syndrome, and PDD—not otherwise specified (PDD-NOS). PDD-NOS was for patients who did not meet the full criteria for either autistic disorder or Asperger syndrome. Children or adults who met one or two of the three major autism criteria showed core deficits in one area, such as social deficits, but did not meet the diagnostic criteria for other symptoms, such as restrictive, stereotypical, and repetitive behaviors, would have been given the diagnosis of PDD-NOS. Research has shown that more than half of the children diagnosed with PDD-NOS were given the diagnosis due to the fewer restrictive and repetitive behaviors they exhibited.



DSM-IV
DSM-5
A. Delay and/or abnormal patterns of development before age 3
B. Qualitative impairment in reciprocal social interactions
C. Qualitative impairment in communication
D. Restricted, repetitive and stereotyped patterns of behavior, interests and activities
A. Persistent deficits in social communication and social interaction across contexts, not accounted for by general developmental delays
B. Restricted, repetitive patterns of behavior, interests, or activities
C. Symptoms must be present in early childhood
D. Symptoms together limit and impair everyday functioning

FIGURE 42.2–1. Social (pragmatic) disorder changes from DSM-IV to DSM-5.

With the advent of DSM-5, PDD was abandoned. In part, this was due to the clarification of diagnostic criteria which were reorganized from three (B to D) to two (A and B) main criteria: (A) persistent deficits in social communication and social interaction, and (B) restricted, repetitive patterns of behavior, interests, or activities. Interestingly, most of the previous PDD diagnostic criteria were rearranged and preserved in DSM-5 ASD (Fig. 42.2–1).

These changes caused considerable stress for some individuals and families as they either did not want to be associated with the term “autism” or feared that they might lose access to services. As will be discussed below, no one was “left out”; however, the change in nosology is still disconcerting for some.

The addition of SCD to DSM-5 was a result of the changes made to the diagnostic criteria to create ASD. In DSM-5, the absence of PDD -NOS and Asperger syndrome meant that there was no longer a place to categorize individuals who only met the DSM-5 ASD “A” criterion (or DSM-IV “D” criterion). Therefore, children or adults who met only the social deficits diagnostic criterion but not the “B” criterion (restrictive, stereotypic, and repetitive behaviors) could not be the new diagnosis: SCD. While there remains a lack of clarity, this diagnosis may allow room for individuals with social interaction deficits and mild or no restrictive and repetitive behaviors. These seeming language disorders remained in the DSM-5 section for neurodevelopmental disorders.

While the diagnosis of SCD may appear to be consistent with the broader concept of pragmatic language impairment, multiple definitions of pragmatic language impairment exist, many of which do not include nonverbal communication. Therefore, further study will be required to determine to what extent SCD is related to the understanding of language pragmatics found in the broader language pragmatics literature.

DIAGNOSTIC FEATURES

SCD is a disruption in the development and use of language pragmatics leading to interference with social functioning (Table 42.2–1).

For this diagnosis, pragmatics refers to the rules that govern social interactions when using both verbal and nonverbal language. It is these rules that allow people to relate to one another reciprocally as well as to create and maintain social transactions. For typically developing children, language pragmatics (initially nonverbal) appear very early and expand rapidly—think of the social smile, visual regard, and pointing as examples. While many think pragmatics are completely intuitive to the typically developing child, it is likely that caregiver reinforcement of these skills increases their quantity, quality, frequency, variability, and utility. In contrast, children with SCD may never exhibit these behaviors, or they are so rare that caregiver reinforcement is not possible. This is rarely a parent/caregiver problem but, rather, a developmental delay or developmental deviation. As a result, children with SCD have early difficulty learning and using even the most basic rules of social communication. While this often begins with delays in nonverbal communication, it generally continues with delays and/or deviations in spoken language, when to listen, how to phrase a question, how to stay on topic, and knowing when the talk is over. As a result of deficits in pragmatics, individuals with SCD may struggle to engage in and/or sustain conversations. Problems may include frequent interruptions, monopolizing conversations, lack of reciprocity, failing to effectively communicate wants and/or needs, or not talking at all. Individuals with SCD may also say things that are inappropriate or unrelated to the conversation at hand. Taken together, these communication problems often make it difficult for individuals with SCD to develop and sustain meaningful social relationships and communicate well with others at school or in the workplace. In addition to the language problems, the communication deficits often lead to frustration (with attendant behavior problems), anxiety, and depression. The symptoms of SCD include the following:

1. Problems using nonverbal and verbal language, such as greeting and sharing information, in ways appropriate for the social context.
2. Impairment in changing communication to match the context or the need of the listener, such as speaking differently in the classroom than on the playground or talking to a child than to an adult.
3. Difficulties following social conventions in conversation and story-telling, such as taking turns in conversations, rephrasing when misunderstood, and knowing how to use verbal and nonverbal signals to regulate the interaction.
4. Difficulty making inferences when something is not explicitly stated, and difficulty understanding the meaning of nonliteral or ambiguous language, such as idioms, humor, and metaphors, and when there are multiple meanings depending on the context.

Table 42.2–1.
DSM-5-TR Criteria for Social (Pragmatic) Communication Disorder

A. Persistent difficulties in the social use of verbal and nonverbal communication as manifested by all of the following:
   1. Deficits in using communication for social purposes, such as greeting and sharing information, in a manner that is appropriate for the social context.
   2. Impairment of the ability to change communication to match context or the needs of the listener, such as speaking differently in a classroom than on a playground, talking differently to a child than to an adult, and avoiding use of overly formal language.
   3. Difficulties following rules for conversation and storytelling, such as taking turns in conversation, rephrasing when misunderstood, and knowing how to use verbal and nonverbal signals to regulate interaction.
   4. Difficulties understanding what is not explicitly stated (e.g., making inferences) and nonliteral or ambiguous meanings of language (e.g., idioms, humor, metaphors, multiple meanings that depend on the context for interpretation).

B. The deficits result in functional limitations in effective communication, social participation, social relationships, academic achievement, or occupational performance, individually or in combination.

C. The onset of the symptoms is in the early developmental period (but deficits may not become fully manifest until social communication demands exceed limited capacities).

D. The symptoms are not attributable to another medical or neurological condition or to low abilities in the domains of word structure and grammar, and are not better explained by autism spectrum disorder, intellectual developmental disorder (intellectual disability), global developmental delay, or another mental disorder.

The communication problems facing individuals with SCD often impair effective communication overall, as well as social participation, academic achievement, and/or occupational performance. The many difficulties with social interactions begin early in life, although the extent of the impairments may not become fully apparent until social communication requirements become more demanding in the preschool or school-age period.

DSM-5-TR criteria require that the symptoms of SCD are not attributable to another psychiatric, other medical disorder, or neurologic conditions, including, but not limited to intellectual disability, global developmental delay, ASD, or any other mental disorders. The deficit in social communication should not be solely attributable to problems in the mechanics of language, as is the case for individuals with language disorder.

Individuals with SCD may show little interest in social interactions. This may appear to be similar to those with ASD. Individuals with SCD may have difficulty adapting language to different listeners (e.g., talking the same way to an adult and to a child) and to different situations (e.g., talking the same way in a classroom as on the playground). They may have trouble making inferences and/or understanding abstractions or implied thoughts or ideas, while they may be readily able to understand that which is stated explicitly. They may not give necessary information when they are speaking to an unfamiliar person, making it difficult to contextualize their utterances. A significant challenge is having difficulty properly gaining the attention of others to make a request or initiate a conversation. People with SCD are often quite literal in their use and understanding of words. This extends to understanding nuanced language and behavior, making inferences with incomplete information, and noticing social subtleties and social cues. As a result, they have difficulty understanding sarcasm, riddles, and humor, and they have trouble telling even the simplest jokes. Some, but not all, individuals with SCD have difficulty understanding nonverbal communication, including gestures, facial expressions, and body posture, in some cases in spite of more than ample vocabulary. It is important to remember that SCD is both an expressive and receptive communication disorder.

Some children with SCD may also have trouble with reading comprehension, despite having reasonably well-developed phonemic awareness and the ability to read well phonetically—they can read it, but they don't understand what they have read. These reading issues may not be noticed until midelementary school or later.

It has been suggested that SCD rarely occurs by itself. Language disorder is the most commonly occurring disorder associated with SCD.

SCD was found to be more common in eighth-grade children with a history of DLD, especially when deficits in pragmatics and structural language occur simultaneously. Having a language disorder of this type during kindergarten was found to increase the risk for SCD during adolescence. However, it was not predictive when “pragmatic and social skills were disproportionately lower than structural language abilities,” according to Ellis Weismer.

Attention-deficit hyperactivity disorder (ADHD) is a common comorbidity associated with SCD. The hyperactivity and inattention problems can aggravate the problems of pragmatic competence. In addition, a lack of social pragmatic skills may lead to children becoming frustrated and having behavior problems.

The following vignettes illustrate SCD in youth with deficits in receptive and expressive nonverbal communication, along with relatively intact structural language.

J is a 6-year-old boy with an age-appropriate vocabulary who often makes comments that are completely out of context. He makes unusual associations with words or phrases and then perseverates on the association. In a similar way, he responds inappropriately to questions from his peers. Taken together, this leads to great difficulty playing with other children. For example, in the midst of playing a game with peers, J said: “What a lovely bouquet.” which he then repeated several times, leaving his peers perplexed. They tried to reengage J, who then just wandered away, repeating the phrase. J’s articulation is clear, and he is able to speak in grammatically correct sentences. He is disappointed and sad because he cannot play with his peers but has little understanding of why.

N is a 17-year-old youth who is often physically bullied by other youth. He is frequently the object of teasing because he is prone to misinterpret the intentions of others and is easily provoked. He has a history of misjudging jokes and even the positive intentions of others. When he speaks, he has virtually no facial expression and very few gestures. He has difficulty initiating and maintaining friendships. He seeks friendships with individuals 4 years older than he but generally does better with children who are much younger. Irrespective of the age group, he has difficulties in social situations. He is aware of this and wants to change so that he can have friends. He plans to follow his therapist's recommendation to avoid the "mean kids" but is not always sure how to tell who they are. He has no repetitive, restricted interests or behaviors, and his cognitive ability is in the "above average" range.

Diagnostic assessment tools for SCD remain quite limited. Studies that screen for SCD and related disorders often use the Children's Communication Checklist (CCC). This 70-item parent-report questionnaire screens for pragmatic abilities and skills within the context of their child's overall language skills. The second edition of this questionnaire, the CCC-2, is one of the few validated tools that measure deficits in pragmatic abilities. Translations of this tool exist for 30 different languages, and normative data for the CCC-2 are available for over 1,400 children from the United States and the United Kingdom.

The Test of Pragmatic Language (TOPL) measures a few characteristics of pragmatic communication, including audience, topic, visual, gestural cues, physical setting, purpose, and abstraction in children between the ages of 6 and 18. The Comprehensive Assessment of Spoken Language measures expressive language skills, such as idiomatic language, nonliteral language, and pragmatic judgment, in children and adolescents between the ages of 3 and 21. However, these instruments are nonideal for diagnostic purposes due to their dichotomous scoring systems, according to Swineford et al. The Pragmatic Rating Scale measures 19 behaviors related to pragmatics, all of which are included in the SCD criteria. This measure includes a 15-minute conversation, derived from the Autism Diagnostic Observation Schedule (ADOS), that is scored from "normal behavior to strikingly abnormal behavior." The Pragmatic Protocol is used for children at a minimum age of 5 and involves a 15-minute observation period in which unstructured conversation occurs. Although the material of these instruments is relevant to SCD, there is a lack of validity and reliability data for either tool.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of SCD can be complex as it must take into consideration the relationship between SCD and psychiatric disorders, especially ASD, intellectual disability, ADHD, and language disorder. Social communication or pragmatic language deficits are common among children referred for psychiatric or psychological assessment. Similarly, comorbidity rates are especially high for children with language disorder, including ADHD, conduct disorder, and traumatic brain injury. Differential diagnosis is especially challenging due to the overlap in symptoms among various psychiatric disorders and the lack of well-validated assessment tools with high levels of reliability. When the DSM-5 was applied to reassess 80 children with DSM-IV-TR PDD diagnoses, 6 children were found to meet SCD criteria, and another 9 children did not meet DSM-5 ASD criteria. Furthermore, six subjects diagnosed with either Asperger disorder, ASD, or PDD-NOS were found to meet DSM-5 criteria for SCD. A study by Mandy et al. (2017) found that their entire sample of 801 children with ASD satisfied criterion B for SCD, and 600 of them also met all four symptom types of criterion A; only 2 of these children did not meet any symptoms of SCD criterion A.

Social communication is one of the two core deficits of ASD. Children with ASD may show adequate structural language abilities yet still have difficulty with pragmatic language, such as pedantic or overly formal speech, verbosity, and reciprocal conversations. For children with ASD, these pragmatic language and social communication difficulties are accompanied by fundamental social deficits, along with restricted interests and repetitive behaviors. The past and/or present symptoms of clinically significant specialized interests and restricted, repetitive behaviors help differentiate ASD from SCD.

Because a diagnosis of ASD can be given to individuals with just a history of fixed interests and repetitive behaviors, individuals who only show significant social and pragmatic language deficits but no present behavioral patterns characteristic of ASD may still be given a diagnosis of ASD. Complicating the differential diagnosis further, stereotyped language, which was previously considered to be a symptom of pragmatic language impairment, is now considered part of the repetitive and restrictive behaviors required for giving a diagnosis of ASD. Finally, some children may show an increase in repetitive behaviors and specialized interests as they grow older, further complicating the differential diagnosis.

When considering a primary language disorder as part of the differential diagnosis, usually children with language disorder show deficits in word knowledge, grammar, and discourse. Discourse includes conversational exchange (reciprocity); narrative deficits in these areas tend to be manifest in social communication problems. However, for children with primary language disorders, social and pragmatic language deficits are thought to be a result of, or secondary to, the structural language impairment. Therefore, a clear relationship between language function and measures of social deficits often supports a diagnosis of language disorder. Other language dysfunction, such as limited vocabulary, prosodic abnormalities, articulation problems, receptive language deficits, and reading problems, increase the likelihood of a language disorder diagnosis.

Some studies have shown group differences in symptom profiles of social communication and pragmatic deficits, and making a differential diagnosis based solely on the basis of social communication, and pragmatic deficits can prove to be challenging. For example, children with Williams syndrome have large vocabularies and are hyperverbal while having fewer problems with stereotyped language, nonverbal communication, social relations, and coherence when compared to children with ASD. An observational study comparing children with SCD and children with language disorder has found that, as a group, children with SCD tend to have more problems with turn taking in conversations, provide no response or inappropriate responses to the communication at hand, and make little use of nonverbal signals when compared to children with language disorder. Much more work is necessary to establish an appropriate level of sensitivity and specificity when assessing social and pragmatic language profiles for the purpose of differential diagnosis, as well as establishing risk factors associated with different clinical populations.

Some have suggested an overlap between SCD symptoms and those in social anxiety disorder. This is due to the apparent uneasiness in social situations in both disorders. However, the time for the onset of symptoms helps differentiate between these two disorders. Children with social anxiety disorder have typically developing social communication skills yet do not utilize them in some settings due to anxiety associated with social interactions. Children with SCD, on the other hand, have early onset of symptoms and usually never had effective social communication.

Although there are no diagnostic tools that specifically screen for SCD according to DSM-5 criteria, some assessment tools have been able to differentiate these diagnoses, according to Yuan and Dollaghan. A study by Morales-Hidalgo et al. identified the ADI-R, the ADOS-2, and a newly developed assessment, the EDUTEA, as three tools that appropriately differentiate ASD/SCD diagnoses from ADHD diagnoses. (The EDUTEA is an 11-item instrument with two factors: social communication impairments and restricted behavior patterns.) High reliability was found for both factors (.93–.95), along with high sensitivity (87.0%) and specificity (91.2%). In addition, the EDUTEA demonstrated sufficient ability to differentiate ASD/SCD diagnoses from ADHD diagnoses, as exemplified by a high sensitivity (83%), specificity (73%), and AUC score (.78).

ETIOLOGY

There is no published systematic research on the etiology of SCD, including examining the heritability and environmental factors associated with SCD using the DSM-5 criteria. The relatively recent labeling of this disorder means that there are few studies examining the familial aggregation and genetic factors associated with SCD. Although the etiology of SCD remains unknown, in the absence of evidence, theories abound.

There is accumulating evidence suggesting that a family history of ASD, language disorder, or specific learning disorder may increase the risk of having social communication and pragmatic language deficits. Many studies are emerging, supporting correlations of impairments in pragmatic language with common gene variants. Duplications at 19p13.12p12 on the short arm of chromosome 19 were identified in a male adult who presented with SCD and intellectual deficits, suggesting that this variant may contribute risk for SCD. In addition, the MET promoter variant rs1858830 C from the receptor tyrosine kinase has been found to be associated with difficulties in social communication in a sample of 748 individuals with ASD from 367 families. However, these genetic variants are not specific to pragmatic language impairments; they are associated with other neurodevelopmental and psychiatric disorders, including ASD, intellectual disorders, and language disorders.

Social inference theory suggests that individuals with SCD, much like individuals with ASD, may have deficits in social cognition, especially in theory of mind (ToM), the ability to make inferences about the mental state of others and use that information to understand and predict their intentions and behaviors. Some have suggested that ToM is an essential precursor for the development of social communication. However, it is equally possible that understanding the mental states of others develops as a result of social communication.

The weak central coherence theory posits that social communication deficits may be associated with a more general processing problem of integrating disparate sources of information into a coherent whole that then allows for specific transactions. This theory suggests that social communication deficits occur due to social communication problems, narrowly focusing on inappropriate or less crucial aspects of the communication while ignoring the bigger picture, which, in turn, makes it difficult for them to use linguistic and social context to derive meaning.

The executive dysfunction theory by Vengas and Davidson suggests that individuals with pragmatic language and communication deficits have a general issue with executive functioning. Executive functions are associated with (but not limited to) activity in the prefrontal cortex, which is associated with high-level cognitive functioning impulse control, behavior monitoring, the flexibility of thinking, abstract thinking, concept formation, problem solving, and planning. The executive dysfunction theory helps explain the great heterogeneity in pragmatic language difficulties experienced by individuals with social and pragmatic difficulties. Executive dysfunction has been implicated in multiple psychiatric disorders, such as ASD and ADHD, each of which is associated with pragmatic deficits.

At this point, there is simply not enough research to support any etiologic substrate of SCD or other social communication or pragmatic language deficits among individuals with SCD.

EPIDEMIOLOGY

There are no reliable prevalence estimates for SCD. It remains unclear as to whether demographic factors such as age, gender, and socioeconomic backgrounds correlate with SCD prevalence estimates. Out of 1,081 children and adolescents seen in a social communication clinic in England, only 8% met SCD criteria, suggesting that the prevalence of this disorder remains very low. A study in the United Kingdom found that 22% of the children attending a language clinic had pragmatic language impairment. However, due to the differences in diagnostic criteria, it is unclear what percentage of these children will also meet the diagnostic criteria for SCD.

Deficits in pragmatic language have been reported without the presence of social deficits or repetitive activities and behaviors. Another estimate showed that over 50% of the children who were given the diagnosis of PDD-NOS had early onset of social communication deficits. In a study of 94 children with PDD-NOS diagnoses, social communication deficits were significantly more present in the children who had comorbid psychiatric diagnoses when compared to those without comorbid disorders. However, none of the above studies used the DSM-5 criteria for SCD; therefore, prevalence is likely to differ from that of SCD.

Table 42.2–2.
Prevalence Estimates: DSM-IV PDD, DSM-5 ASD, DSM-5 SCD

	% DSM-IV PDD	% DSM-5 ASD	% DSM-5 SCD	% DSM-5 ASD + SCD
Population				
Total	2.64	2.20	0.49	2.69
GPS	1.89	1.46	0.49	1.95
HPG	0.75	0.75	0.00	0.76
DSM-IV PDD Subtype

Reprinted from Kim YS, Fombonne E, Koh YJ, Kim SJ, Cheon KA, Leventhal BL. A comparison of DSM-IV pervasive developmental disorder and DSM-5 autism spectrum disorder prevalence in an epidemiologic sample. *J Am Acad Child Adolesc Psychiatry*. 2014;53(5):500–508. doi: 10.1016/j.jaac.2013.12.021.

A field trial comparing the prevalence of ASD using the DSM-5 criteria and PDD using the DSM-IV criteria showed a decrease in the prevalence of ASD in one site. Nevertheless, when the prevalence of ASD was combined with the prevalence of SCD, the prevalence was not significantly different from that of DSM-IV PDD. This suggests that the decrease, if any, in the estimated prevalence of ASD may be accounted for by the inclusion of DSM-5 SCD.

In a total population sample from Korea, Kim et al. initially diagnosed the children using DSM-IV criteria. They were subsequently rediagnosed using DSM-5 criteria. They found that the population prevalence of SCD was 0.49%. In addition, they reported that of the 1.00% previously diagnosed with PDD-NOS, 0.32% met the criteria for SCD, while of the 0.60% diagnosed with Asperger syndrome, 0.05 met criteria for SCD (0.55% met ASD criteria) (Table 42.2–2).

DEVELOPMENT AND COURSE

The diagnostic category of SCD is so recent that there are not sufficient longitudinal studies to give a clear picture of the development of SCD.

The diagnosis of SCD is difficult prior to the development of speech as a tool for complex social interactions between the ages of 3 and 5. However, for those children who are speaking by age 2 and those children with limited social reciprocity, SCD should be a part of the differential diagnosis during evaluations. By 4 or 5 years old, most children should have developed sufficient social communication and language skills. Those who have not done so should undergo thorough evaluations with consideration of SCD as a diagnosis, among other NDDs. While most cases are evident early in childhood, some milder forms of SCD may escape detection until adolescence, when the social communication and language demands intensify. Although SCD requires relatively intact structural language and impaired social communication, there is great heterogeneity in the severity and patterns of symptom manifestation among those who are diagnosed with SCD. One study found that 64 out of 66 children who had been previously diagnosed with DSM-IV PDD-NOS had “one distinct symptom pattern, namely social impairments without significant repetitive and stereotyped behaviors.” As a group, children with ASD tend to have more severe social communication and pragmatic language deficits than children with SCD. Children with language disorder, in turn, tend to show milder symptoms of social and pragmatic language deficits than children with SCD.

With no epidemiologic longitudinal follow-up studies, it is difficult to describe the long-term outcome of SCD. Given the heterogeneity of symptoms, it is likely that outcomes will differ greatly. Clinical experience suggests that some children with social and pragmatic skills deficits improve considerably over the course of development while others have persistent social communication skills deficits extending into adulthood.

In general, studies suggest that children with pragmatic language difficulties tend to perform better in academics when compared to children with structural language problems. In addition, children with social communication deficits may also struggle with written expression and reading comprehension. Gilmour et al. found that deficits in pragmatic language skills were frequently observed in children who were persistently disruptive in school settings. There is some evidence suggesting that pragmatic language difficulties in elementary school years may be associated with emotional and behavioral difficulties, higher rates of referral for psychiatric and psychological assessments, and longer duration attending special education.

Social communication problems rarely occur in the absence of other psychiatric disorders. Comorbid disorders, as well as other risk factors, are likely to affect the developmental course and prognosis of SCD.

TREATMENT

Social (pragmatic) deficits rarely occur without other cooccurring behavioral or emotional difficulties. These behavioral and emotional problems may serve as risk factors for further social communication difficulties, and social difficulties, in turn, may accentuate the cooccurring behavioral and emotional problems.

Since SCD is relatively uncommon and only recently recognized as a separate clinical disorder, diagnosis-specific treatments are not readily available. However, this is not unusual and represents the situation for most neurodevelopmental disorders for which most treatments are directed at specific symptoms rather than the diagnosis. As a result, in the current clinical context, the clinician should consider any treatments that are focused on improving social as well as social pragmatic language functions.

One randomized controlled trial examined the social outcomes of children with social communication deficits (both with symptoms of SCD and ASD) who received intensive, individualized, multifaceted interventions as compared to children who received treatment as usual.

The intervention focused on developing (1) social interaction skills and social understanding, (2) verbal and nonverbal pragmatic skills, and (3) language processing skills. The children received up to 20 sessions from specialized speech–language professionals and trained assistants. The children who received the experimental intervention showed significant improvement in blind ratings of communication skills, teacher ratings of learning behaviors, and parental ratings of social and pragmatic skills. There were, however, no significant changes in the standardized assessment measures of social communication, which may be due to the lack of sensitivity of these measures to detect change.

Several treatment options have been proposed for children with social communication and pragmatic language difficulties who also present behavioral/emotional problems. Several behavioral interventions and cognitive behavioral treatment programs have been proposed, involving multiple collaborators, including speech–language therapists, mental health professionals, family members, teachers, and peers. Irrespective of who implements the treatment, significantly greater improvements have been observed in children who begin treatment early, with maximum benefits occurring in children who begin between the ages of 3 to 4.

The Social Communication Intervention Programme (SCIP) is a manualized, theoretically driven intervention for children with difficulties in social communication. In one study of school children with difficulties related to pragmatics and social communication, SCIP was more effective in addressing pragmatic competence as well as modifications in social communication and language skills; however, no improvements in language functioning were observed. A more recent SCIP feasibility study found that all 15 school-aged children made significant progress according to the practitioner ratings; parent report suggests that 1 of the 15 children did not make progress.

Functional communication training is a behavioral technique that has been used to treat problem behaviors associated with communication problems. After a functional analysis is conducted to identify the environmental triggers that evoke the problematic behavior, a targeted behavioral reinforcement intervention is initiated. Usually, the intervention focuses on increasing socially acceptable communicative responses and behaviors in a variety of social contexts.

Cognitive behavioral therapy (CBT) may also be useful, especially in the presence of anxiety and mood symptoms or specific comorbidity that is amenable to CBT.

Didactic training in social skills on its own has yielded few meaningful social changes. This is likely because individuals with SCD do not generally have impaired knowledge of social norms and appropriate behaviors. Interventions targeting underlying deficits, developing strategies to minimize distracting information, or making explicit important verbal and nonverbal cues may be more beneficial.

A social cognitive reinforcement program has been developed for children with SCD. This intervention has three components: executive function training, social cognition training, and communication skills training. It is divided into three steps: introduction (session 1), development (sessions 2 to 7), and conclusion (session 8). Twenty-two children with SCD participated in a comparison study between this intervention and a typical social skills training program. The children who engaged in the social cognitive reinforcement program improved significantly in multiple areas: nonverbal communication, self-assertion, comprehension, and self-control, as demonstrated by notable improvements measured by the Reading the Mind in the Eyes Test, the Children’s Color Trails Test, a picture arrangement task, and a picture completion task. Furthermore, at the 3-month follow-up, significant improvements in executive functioning, pragmatic communication, and social skills were observed in the children who participated in the social cognitive reinforcement program, suggesting that a multicomponent intervention may be the most ideal treatment program for children with SCD.

SUMMARY

SCD is a recent addition to psychiatric nosology. While the clinical presentation is characterized by considerable heterogeneity, SCD represents a fundamental deficit in the ability to use language pragmatics to fully engage in adaptive, reciprocal social interactions. SCD is a relatively rare condition with a prevalence in the range of 0.5%. SCD appears to have an onset in early childhood, and, for many, it likely has a chronic course extending through the lifespan. The etiology of SCD is unknown, and, to date, there are no diagnosis-specific treatments. However, symptom-directed interventions appear to show considerable promise.

42.3 Speech Sound Disorder

EMIKO KOYAMA, PH.D., MAHLIQA ASHRAF, H.B.SC., TUANA KANT, M.SC., AND JAMES L. KENNEDY, M.D., F.R.C.P.C., F.R.S.C.

Speech sound disorder is the most common communication disorder in childhood. Children with speech sound disorder do not correctly produce the speech sounds that are expected for their age, developmental stage, and dialect. Sounds may be omitted (e.g., saying *hou* for *house*), substituted for other sounds (e.g., saying *yewo* for *yellow*), or distorted because they are produced in an atypical way (e.g., saying /sh/ with too much air escaping from the sides of the mouth). Often, the speech sound errors occur in systematic patterns. For example, consonants that should involve a steady airflow instead may have an interrupted airflow (e.g., *bacuum* for *vacuum*), or consonants that should appear at the end of words may instead be omitted (e.g., *be* for *bed*). In severe cases of speech sound disorder, speech may be completely incomprehensible to others.

Linguistic and motor learning, as well as their integration and coordination, are essential for speech-sound development. Linguistic learning presumably involves the gradual and implicit acquisition of a complex rule system that underlies the representation, perception, and production of speech. Children acquire knowledge about the individual speech sounds that comprise a particular language and their permissible contrasts and combinations. Children also induce the regularities governing syllable and word stress and the intonation patterns (melody) of speech.

Speech sound development also involves considerable motor learning. Speech production entails the quick, accurate, and coordinated actions of the many muscles that support breathing, voicing, and articulation of speech sounds. Major articulators that shape speech sounds include the tongue, lips, upper teeth, the gum behind the upper teeth (alveolar ridge), the hard and soft palates, the uvula, the pharynx, and the glottis (the opening between the vocal cords). Eventually, most adults learn to control the complex coordination of these fine motor activities well enough to enable the production of intelligible speech at rates as high as 250 words per minute.

Children with speech sound disorder generally develop speech sounds in a typical sequence but with a delayed onset and slow rate of growth. Early words generally include consonant sounds designated as the *early eight* (/m/, /b/, /y/, /n/, /w/, /d/, /p/, and /h/), which are also commonly used during the babbling stage from about 6 months of age. As development continues, the *middle eight* consonant sounds (/t/, /ng/, /k/, /g/, /f/, /v/, /ch/, and /j/) are mastered gradually, followed by the *late eight* (/sh/, /th/ [two variants], /s/, /z/, /l/, /r/, and /zh/). Children may not achieve full mastery of the late eight consonant sounds until 7 or 8 years of age. Throughout the course of typical development, children may produce speech sounds incorrectly and inconsistently.

Word formation normally proceeds in a systematic fashion. The first words that children use generally produce consist of simple sequences of consonants (C) and vowels (V) that comprise syllables of the forms CV (e.g., bye), VC (e.g., up), or CVC (e.g., dog) and short repetitive sequences of the form CVCV (e.g., dada). More complex syllable and word shapes are gradually mastered, such as those with multiple, nonrepetitive syllables and consonant cluster sequences, such as /thr-/, /kl-/, /-rst/, or /-nt/. Vowels are generally thought to be acquired early, and most studies suggest that vowel production is relatively accurate by 2 years of age. As such, numerous vowel errors made beyond age 2 years may be early warning signs of impaired speech.

Speech sound errors may also be described in terms of phonologic processes or rules that encompass a pattern of errors. For example, young children often use a phonologic process of final consonant deletion in which they regularly omit consonants at the end of words. This deletion process is often used by young children but may usually disappear from their speech by 3 years of age. Similarly, there are other common processes that gradually disappear during normal development, including reduplication (repetition of a syllable to form a multisyllabic word, e.g., *bahbah* for *bottle*), unstressed syllable deletion (omission of a syllable that is not stressed, e.g., *nana* for *banana*), stopping (use of an interrupted airflow for sounds that should have a continuous airflow, e.g., *tee* for *see*), consonant harmony (e.g., using a sound similar to one that occurs elsewhere in a word, e.g., *tat* for *cat*), and consonant cluster reduction (omitting or simplifying sounds in a consonant cluster, e.g., *top* for *stop*).

These phonologic processes all occur regularly in the speech of young children, but all are usually overcome before 5 years of age.

Even if a child mispronounces words, it may not affect the overall comprehension of the child's utterances. If a child's spoken word or phrase cannot be understood, the child's speech is said to be *unintelligible*. Intelligibility is influenced not only by the produced speech sounds but also by other factors, such as pragmatic context and the complexity of the sentence. In normal speech development, roughly half of children's speech is considered intelligible at about 2 years of age, roughly 75% is intelligible by 3 years of age, and by age 4 years, nearly all of the child's spoken language becomes intelligible. If less than two-thirds of the child's utterances are intelligible by age 4, clinical attention may be warranted.

COMPARATIVE NOSOLOGY

Speech sound disorder in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders, Text Revision* (DSM-5-TR) largely corresponds to phonological disorder in the revised fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR). The designation of *speech sound disorder* is typically reserved for speech sound problems with no known cause, which are thought to reflect difficulties in learning the regularities of phonology (the sound system of a language). Speech sound disorder may also be designated when causes are known (e.g., hearing impairment), but the speech impairment exceeds what is expected given the known cause. The 10th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) provides the category of *specific speech articulation disorder* for speech problems of unknown etiology and designates a different category for speech impairment arising from sensory, structural, or neurologic conditions. The 11th edition of the ICD includes *developmental speech sound disorder*, which has similar criteria to DSM. In the research literature, terms such as (developmental) phonological disorder, (functional) articulation disorder, developmental verbal dyspraxia, and childhood apraxia of speech are commonly used in association with speech sound disorder.

EPIDEMIOLOGY

The prevalence of speech sound disorder is around 5% to 10% in preschoolers, 3% in 6- to 7-year-old children, and 0.5% in 17-year-old children. Estimates, however, vary widely in the research literature, reflecting the diverse criteria and samples that have been used across studies. Slightly more than half show problems only in speech sound production; the remainder also have language difficulties. Overall, speech sound disorder occurs far more frequently than speech impairment with known structural or neurologic origins.

The literature consistently shows that speech sound disorder occurs more often in boys. Estimates for sex ratios are as high as 4:1 and as low as 1.5:1. Speech sound disorder also shows high rates of familial aggregation. Approximately 20% to 40% of children with speech sound disorder have at least one immediate family member who is also affected. There is evidence in favor of genetic contributions to familial aggregation, but environmental factors may also play a role. Familial risk factors such as low maternal education have also been identified as potential risk factors.

ETIOLOGY

The majority of children with speech sound disorder has no known cause. Proposals regarding causation typically focus on many of the same factors considered as possible causes for language disorders, including subtle brain abnormalities, genetic influences, environmental factors, neurodevelopmental immaturity, linguistic factors, and auditory processes. In addition, speech motor control and speech mechanism factors have also been entertained as possible causes.

Speech sound disorder most likely has multiple causal determinants. Although some evidence supports each proposed determinant, no single one is implicated in all cases of speech sound disorder. The idea that brain abnormalities may be responsible for speech sound disorders is supported primarily by indirect evidence, which includes reports of associated soft neurologic signs at higher than normal rates and findings of structural or functional brain abnormalities in children with related disorders, such as language disorder and reading disorder. The evidence in support of genetic factors comes from a variety of methods, including pedigree, twin, adoption, and linkage studies. Recent studies have found susceptibility of speech sound disorder genes in chromosomes 3, 6, and

15, which are also thought to be candidate regions for dyslexia. One of the genes that have been extensively associated with speech problems is the *FOXP2* gene on chromosome 7. Children with changes or mutations on the *FOXP2* gene may experience difficulties producing sequences of speech sounds and may also experience delays in language, social, and motor development. The prevalence of *FOXP2*-related speech problems is estimated to be relatively rare, affecting 1 to 2 in 1,000 people. The advancement of work on genetic influences will probably stimulate corresponding advances in the understanding of environmental determinants. At present, however, no conclusive evidence links specific environmental factors to speech sound disorders, although it is reasonable to assume that such factors contribute in as-yet unspecified ways.

Neurodevelopmental immaturity is suggested by the fact that children with speech sound disorder usually follow the same sequence in speech sound development as children without the disorder, albeit at a slower rate. Additional indirect support comes from findings of soft neurologic signs and subtle deficits in motor skills. Children with speech sound disorders may also have linguistic deficits that interfere with efficient learning of the regularities of phonology (e.g., permissible sounds, combinations, or positions of occurrence) from the available language input. Difficulties with auditory discrimination and perception or temporary hearing loss may also contribute to some cases of speech sound disorder. Children with speech sound disorder also show elevated rates of subtle abnormalities in the structure and function of the speech mechanism, but it is not yet known whether these abnormalities are causes or just correlates of the disorder.

DIAGNOSIS AND CLINICAL FEATURES

A diagnosis of speech sound disorder is given when a person experiences persistent difficulties in speech sound production due to different degrees of impairment in phonologic knowledge and coordination of movements involved in speech. The onset of speech sound problems is during childhood. The speech sound production is impaired for what is expected based on the speaker’s age and dialect and cannot be attributed to medical or neurologic conditions such as cerebral palsy, cleft palate, traumatic brain injury, or hearing impairment. A further criterion is that the speech sound difficulties must interfere with social communication, academic achievement, or occupational success. Speech sound disorder ranges in severity from mild, in which errors occur on one or two sounds and speech intelligibility is hardly affected, to severe, in which errors occur on most sounds and speech intelligibility is significantly impaired.

A delayed onset and slow rate of speech sound development are typical of most children with speech sound disorders. However, the course and sequence of development usually resemble those of typically developing children. Simple syllable and word shapes are gradually elaborated to include more complex shapes. The rate of acquisition may be slow but usually follow the typical sequence, with the early eight consonant sounds usually developing first, followed by the middle eight, and then the late eight consonant sounds. The errors in speech sound production resemble those that occur in normal development, but the relative distribution of omissions, substitutions, and distortions may be somewhat different. Children with speech sound disorder generally use phonologic processes that also occur in normal development but may use these processes well beyond the age at which they normally disappear. Children with speech sound disorder also sometimes use unusual or idiosyncratic phonologic processes that are not observed in normal development.

Ramon was a talkative, likable 3 year old with virtually unintelligible speech, despite his normal hearing and language comprehension skills. Ramon's level of expressive language development could not be determined because his speech was so difficult to understand. The rhythm and melody of his speech, however, suggested that he was trying to produce multiword utterances, as would be expected at his age. Ramon produced only a few vowels (/ee/, /ah/, and /oo/), some early developing consonants (/m/, /n/, /d/, /t/, /p/, /b/, /h/, and /w/), and limited syllable shapes (V, CV, and CVCV). This reduced sound repertoire made many of his spoken words indistinguishable from one another (e.g., he said *bahbah* for *bottle*, *baby*, and *bubble*, and he used *nee* for *knee*, *need*, and *Anita* [his sister]). Moreover, he consistently omitted consonant sounds at the end of words and in consonant cluster sequences (e.g., /tr-/, /st-/, /-nt/, and /-mp/). On occasion, Ramon reacted with frustration and tantrums to his difficulties in making his needs understood.

Kent was a pleasant, cooperative 5-year-old boy who had been diagnosed with a speech sound disorder when he was a preschooler. His hearing and language comprehension skills were within normal limits. However, he showed some mild expressive language problems in the use of certain grammatical features (e.g., pronouns, auxiliary verbs, and past-tense word endings) and in the formulation of complex sentences. He correctly produced all vowel sounds and most of the early-developing consonants but was inconsistent in his attempts to produce later-developing consonants (e.g., /r/, /l/, /s/, /z/, /sh/, /th/, and /ch/). Sometimes, he omitted them; sometimes, he substituted other sounds for them (e.g., /w/ for /r/ or /f/ for /th/); occasionally, he even produced them correctly. Kent had particular problems in correctly producing consonant cluster sequences and multisyllabic words. Cluster sequences had omitted or incorrect sounds (e.g., *blue* might be produced as *bue* or *bwue*, and *hearts* might be said as *hots* or *hars*). Multisyllabic words had syllables omitted (e.g., *efant* for *elephant* and *getti* for *spaghetti*) and sounds mispronounced or even transposed (e.g., *aminal* for *animal* and *lemon* for *melon*). Strangers were unable to understand approximately 80% of Kent's speech. Fortunately, Kent often spoke more slowly and clearly than usual when he was asked to repeat something, as he often was.

Natasha was a shy, reserved 8-year-old girl with a history of significant speech delay. During her preschool and early school years, she overcame many of her earlier speech errors. A few late-developing sounds (/r/, /l/, and /th/), however, continued to pose a challenge for her. Natasha often substituted /f/ or /d/ for /th/ and produced /w/ for /r/ and /l/. Overall, her speech was easily understood despite these minor errors. Nonetheless, she was often reluctant to speak in front of others because of the teasing she received from her classmates about her speech.

Other language, learning, and developmental disorders may co-occur with speech sound disorder. Language disorder, especially deficits in expressive language, frequently co-occurs with speech sound disorder. Children who have both speech sound disorder and language disorder are at increased risk for other problems, such as reading, spelling, and other learning problems, attention deficit hyperactivity disorder (ADHD), and developmental coordination disorder. Children with isolated speech sound disorders are at a relatively small risk for severe academic, behavioral, or psychiatric disorders. If a speech sound disorder persists into adulthood, it may contribute to social anxiety disorder.

PATHOLOGY AND LABORATORY EXAMINATION

There are no laboratory tests that can provide a diagnosis of speech sound disorder. When necessary, specific laboratory tests may help identify and document an underlying neurologic condition that is responsible for apraxia or dysarthria.

DIFFERENTIAL DIAGNOSIS

The most important task in the diagnosis of speech sound disorder is to judge if speech sound production is inappropriate for the age and dialect of the speaker. The judgment may be challenging because the speech of children with speech sound disorder often resembles that of younger children who are developing normally. The same speech errors that may indicate disorder in a 6-year-old child may also indicate typical development in a 4-year-old child. Thus, it is critical to carefully compare a particular child’s pattern of speech sound errors to the normal patterns of speech sound development in children.

One must also carefully consider the dialect spoken by the child. Sound differences that may be quite acceptable in one dialect may suggest disorder in another. For example, the production of *caht* for *cart* is acceptable for speakers from Boston but not for those from most other parts of North America.

One of the challenges facing clinicians is how to diagnose speech sound disorders in bilingual children. Depending on such factors as the child’s first language background and the timing of acquisition of the second language, even typically developing bilingual children may exhibit more frequent and atypical phonologic error patterns compared to their same-age monolingual peers. Research is needed to establish the typical and atypical speech patterns of children acquiring a second language. Meanwhile, an assessment of speech sound production skills in English and the child’s other language, accompanied by a careful history, may lead to a correct diagnosis.

The diagnostic assessment should also include a hearing test and an oral examination. The hearing test identifies temporary or permanent hearing difficulties that may require medical or other interventions to enhance the prognosis for the development of understandable speech. The results from the oral examination may help clarify whether the speech sound production problems are developmental, structural, or neurologic in origin. For example, children with neurologic conditions may be slow or inaccurate in performing various speech and nonspeech movements (e.g., sequencing syllables, as in *putuku*; protruding the tongue; or rounding the lips) or may show signs of muscle weakness or paralysis. Drooling, feeding, or swallowing problems suggestive of dysarthria, may also be observed or reported in the history. During the oral examination, the diagnostician may also identify structural abnormalities in the mouth, such as tumors or submucous clefts of the palate, which may need to be considered in the overall management of the child.

Selective mutism is an anxiety disorder that is characterized by the consistent failure to speak in specific social settings. Children with speech sound disorder may not speak due to embarrassment about their speech impairments. However, children with selective mutism typically exhibit normal speech in settings where they feel “safe,” such as with family or close friends.

Screening for possible co-occurring communication disorders is also important for children diagnosed with speech sound disorders. When an intellectual developmental disorder is suspected, a cognitive assessment may help confirm or rule out this diagnosis. In cases in which speech difficulties are in excess of those expected for a particular degree of intellectual disability, a diagnosis of co-occurring speech sound disorder may be made.

A practitioner should make a referral to a speech–language pathologist for assessment of speech sound production skills when (1) a 2 year old uses little or no speech, (2) a 3 year old is poorly understood by familiar members of the family, (3) a 4 year old is poorly understood by peers and strangers, (4) a child of any age seems to be withdrawing from social interactions as a result of teasing or frustration associated with speech difficulties, (5) a parent or teacher is concerned about a child’s speech, or (6) a child (or adult) experiences a sudden deterioration in speech production skills. The last may be the first warning sign of a developing neurologic condition and, therefore, also warrants referral for neurologic examination.

COURSE AND PROGNOSIS

Diagnosis may occur as early as 2 years of age in severe cases of speech sound disorder, which may be accompanied by co-occurring language involvement. However, diagnosis around 4 years of age is more usual. Speech sound disorders show considerable variability in severity, course, and outcome. In approximately 75% of mild-to-moderate cases, speech sound production skills normalize by 6 years of age, with or without intervention. Thus far, no specific predictors of normalization have been identified among the various speech, hearing, oral, cognitive, linguistic, or psychosocial variables that have been investigated. For children whose speech has not normalized by 6 years of age, speech sound development proceeds in spurts and plateaus until 8 or 9 years of age. If normalized speech has not been achieved by then, residual articulation problems often persist into adulthood unless successfully treated. These residual errors usually involve distortions of later-developing sounds, such as /l/, /r/, /s/, /z/, /sh/, /ch/, and /th/. Specifically, distortions of the sounds /s/, /z/, /sh/, and /ch/ are termed *lisps*. Residual errors often have little effect on speech intelligibility but may influence others to erroneously perceive a speaker as lazy, immature, or of low intelligence.

Children with mild-to-moderate speech sound disorders are at relatively little risk for adverse long-term outcomes. Although speech typically normalizes by 8 to 9 years of age, subtle deficits in the speed and accuracy of articulation during complex speech tasks (e.g., rapid pronunciation of multisyllabic words) may remain detectable into adulthood but have little functional impact. Overall, language, cognitive, academic, psychosocial, and psychiatric outcomes are usually within the normal range for adults with a history of mild-to-moderate speech sound disorder.

Children with severe speech sound disorders that persist to school age are at a greater risk for poor outcomes. They may not develop adequate phonologic awareness skills (perception, identification, and mental manipulation of speech sounds), which, in turn, may lead to problems in learning to read and spell. Parents and teachers should carefully monitor the reading and spelling development of school-aged children with severe, persistent speech sound problems. If required, reading and spelling performance can then be fostered through explicit instruction in phonologic awareness. It is not yet clear whether severe speech sound disorders are associated with an increased risk for adverse psychosocial or psychiatric outcomes.

Children with co-occurring language disorders are, however, known to have elevated risk for adverse long-term outcomes in communicative, academic, psychosocial, or psychiatric functioning. Those with receptive difficulties are at the greatest risk.

TREATMENT

Treatment is typically recommended for children with moderate-to-severe speech sound disorders. A speech–language pathologist may provide the treatment directly to the child or indirectly through paraprofessionals, parents, teachers, peers, or other volunteers who are taught how to provide treatment for the child. Although there are many intervention techniques, styles, and programs that have been advocated, two main approaches to treatment are discernible.

The *traditional approach* is typically used with children who produce substitution or distortion errors for just a few sounds. In this approach, the child participates in activities that highlight the auditory and motor characteristics of a particular sound. The child then practices the production of the sound while the clinician provides feedback and cues concerning the correct placement and movement of the articulators. Treatment is discontinued once the child produces the new sound accurately in spontaneous speech.

A *phonologic approach* is usually chosen for children with patterns of multiple speech sound errors that are described by phonologic processes (e.g., final consonant deletion or consonant cluster reduction). In this approach, the child participates in activities that demonstrate the communicative value of correctly using certain classes of sounds, such as final consonants or consonant clusters. The child then practices the production of various final consonants or clusters in meaningful communicative situations until the targeted groups of sounds are incorporated into the child's phonologic system. Treatment is discontinued once the child uses the new classes of sounds correctly and consistently in everyday speech.

Traditional and phonologic approaches have proven effective in accelerating the rate of speech sound development. However, not all variations of these approaches have yet been subjected to rigorous investigations of their efficacy. Additional research is also needed to compare the relative merits of various techniques for children with different profiles of speech errors, although some work of this nature has begun to appear in the literature. Overall, treatment success depends on whether the new speech skills become established as automatic patterns of production. A key factor in achieving this goal may be the extent to which a child or adolescent is motivated to change existing speech patterns.

In addition to speech sound intervention, children with co-occurring language disorder may need interventions to promote language or fluency. Few studies have systematically evaluated the efficacy of such joint interventions. It is possible that speech production gains may occur as an additional benefit of language intervention that did not focus specifically on speech sound production.

ACKNOWLEDGMENTS

This chapter was written in memory of the late Dr. Joseph H. Beitchman, who continues to inspire us with his dedication, devotion, and extensive research work in childhood language disorders.

42.4 Stuttering

EMIKO KOYAMA, PH.D., MAHLIQA ASHRAF, H.B.SC., JAMES L. KENNEDY, M.D., F.R.C.P.C., F.R.S.C., AND TUANA KANT, M.SC.

Stuttering is a condition in which the flow of speech or fluency is disrupted by involuntary speech–motor events. Stuttering may include a variety of specific dysfluency types, such as sound and syllable repetitions, sound prolongations, dysrhythmic phonations, and complete blocking or unusual pauses between sounds and syllables of words. More severe forms of stuttering are frequently accompanied by a variety of struggle behaviors, commonly referred to as *accessory*, or *secondary*, characteristics of the disorder. These struggle behaviors may be observed at the respiratory, phonatory, or articulatory level of the speech mechanism and may manifest themselves in disordered breathing, glottal fry (abnormal voice quality), lip pursing, and tongue clicking. Additional behaviors, such as eye blinks, facial grimacing, head jerks, and abnormal body movements, may be observed before or during instances of disrupted speech. In addition to the core and secondary physical symptoms of stuttering, the intended communication is often further altered or distorted by linguistic avoidance due to anticipatory sound or word fears. Linguistic avoidance is a commonly observed feature of stuttering, which results in word substitution and circumlocution as the individual approaches the feared sound or word during the communicative attempt. Furthermore, it has been reported that varying levels of both utterance length and temporal complexity function to modulate stuttering frequency in adult stuttering speakers. Similarly, situational avoidance is often characteristic of chronic stuttering, and the type of communicative situation often influences the amount and severity of stuttering. Stuttering patterns are extremely variable, ranging from mild, occasional dysfluencies in speech to severe stuttering that renders communication all but impossible for the affected individual and often results in serious psychological difficulty and social withdrawal. Moreover, the person who stutters may exhibit widely fluctuating periods and severity of dysfluency within the course of a day, depending on the communicative situation, anxiety level, fatigue level, and other associated variables, making stuttering a multifactorial disorder. It is to be noted that stuttering severity is not solely a measure of the frequency of observed stuttering but is usually a function of the communicative hardship it places on the speaker. In other words, an individual employed in an office setting who exhibits a stuttering rate of 15% may feel less handicapped than an airline pilot who is 4% dysfluent, but whose fluent communication is critical. Most recently, treatment efficacy studies of stuttering have begun to utilize measures of functional communication and quality of life to supplement traditional data gathered from counts of stuttering frequency.

HISTORY AND COMPARATIVE NOSOLOGY

Psychiatric syndromes can be defined from the point of view of the observer or the patient. Depressed individuals may not look depressed, but if they report subjective symptoms sufficient to meet criteria, a diagnosis of a depressive disorder can be made. Likewise, stuttering can be defined from the point of view of the listener or the speaker. The speaker’s sense of subjective distress or loss of control of their speech apparatus reflects an approach to nosology that focuses on the speaker’s experience. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM) focuses on the observer’s point of view—that is, on the observable behaviors that are impinging on the patient’s quality of life.

In both DSM-III and DSM-III-R, stuttering was placed in the category of disorders usually first evident in infancy, childhood, or adolescence. In both of these systems, stuttering was coded on axis I, along with clinical psychiatric syndromes. This remains controversial as stuttering is not commonly viewed as a psychiatric disorder among speech–language professionals, and speech–language pathologists have argued that stuttering should not be included in DSM at all.

In DSM-IV-TR, stuttering is categorized as a communication disorder. This is consistent with the speech–language pathology classification, in which all speech and language disorders are kept within the same category. However, it remains to be shown that it belongs in this category; aside from the similarity of causing communicative difficulties, stuttering may pathologically differ from the other communication disorders in this category. The 10th revision of the *International Statistical Classification of Disease and Related Health Problems* (ICD-10) separates stuttering (stammering) from the speech and language disorders and places it in the category of other behavioral and emotional disorders with onset occurring in childhood and adolescence. The diagnostic criteria in ICD-10 are similar to the DSM-IV-TR diagnostic criteria, but a few differences are notable such as the removal of age-dependent criteria in DSM-IV-TR.

DSM-IV-TR requires that the disorder interferes with academic or occupational achievement or social communication for a diagnosis, whereas the ICD-10 diagnosis applies only if it is severe enough to cause notable disturbances in fluency. ICD-10 requires a minimum duration of 3 months of consistent symptomology; DSM-IV-TR has no duration criterion. DSM-IV-TR further specifies that the disturbance must exceed what is appropriate for the individual’s age, and, if a speech–motor or sensory deficit is present, the speech difficulties must exceed those usually associated with these problems. ICD-10 has an additional category for cluttering, which is not accorded separate status in DSM-IV-TR.

In DSM-5 and its text revision (DSM-5-TR), stuttering is rephrased as childhood-onset fluency disorder (stuttering) and categorized within the communication disorders. Stuttering is defined by regular uncontrolled disturbances in the normal fluency and patterning of speech that are inappropriate for the individual’s age and language skills, persist over time, and are characterized by frequent and marked occurrences of one (or more) of the following: phoneme and syllable repetition, with prolonged vowels and consonants, aberrant interjections and pauses between words and syllables, abrupt pauses in speech, linguistic avoidance of words that triggers stuttering, words produced with excessive physical strain, and monosyllabic repetitions (e.g., “I-I-I see him”).

DSM-5 and DSM-5-TR removed the use of interjectional phrases such as “um,” “ah,” and “you know” as part of the diagnostic definition of stuttering. DSM-5-TR also states the disturbance should not be attributable to a speech–motor or sensory deficit, dysfluency associated with a neurologic insult (stroke or hemorrhage), another medical condition (neurogenic stuttering), or better explained by another mental disorder.

The 11th revision of the *International Statistical Classification of Disease and Related Health Problems* (ICD-11) also contains the diagnosis of developmental speech fluency disorder, with similar criteria to the DSM-5-TR.

With onset in early developmental periods, these disturbances facilitate the comorbid development of social anxiety when speaking, which results in limitations to effective communication, social participation, or academic, or occupational performance, individually or in any combination. DSM-5 included the presence of social anxiety or situational avoidance as part of the diagnostic criteria for stuttering.

EPIDEMIOLOGY

Surveys conducted chiefly in the United States and Europe indicate that the prevalence of stuttering in the general population is approximately 1%. Although data regarding incidence vary widely, most specialists would agree that the likelihood of an individual ever exhibiting some form of stuttering is between 3% and 4%. Of those who begin to stutter, the majority, around 80%, stop by adulthood. The estimated percentages of spontaneous recovery in stuttering, again, vary widely because of differing definitions of stuttering and normal nonfluency, age groups studied, and data collection techniques. Several studies have estimated spontaneous recovery to be as high as 80%. Stuttering is more prevalent among boys than girls, with the ratio of boys to girls among U.S. schoolchildren being between 3:1 and 5:1. Current studies have challenged the above estimates of prevalence, incidence, and gender ratios. Among other factors, it has been postulated that most of the risk for stuttering onset is over by age 5. Even in its earliest stages, stuttering has been shown to be both qualitatively as well as quantitatively different from normal dysfluency.

A high familial incidence is indicated by the presence of stuttering among the relatives of approximately 50% of individuals who stutter. In addition, a high degree of concordance of stuttering exists in identical twins. Individuals who stutter appear to have normal developmental histories, except for speech and language. Numerous studies have demonstrated that young stuttering children are somewhat delayed in early language and articulation development; however, studies of older stuttering children appear to demonstrate that language skills are once again age appropriate. With regard to personality and social and emotional adjustment, children who stutter are often regarded by their parents or primary caregivers as nervous and prone to specific fears. They are often described as overly sensitive to their environment. Adults who stutter tend to be somewhat more anxious and emotionally reactive than their nonstuttering peers. For the most part, studies relating intellectual ability to stuttering are inconclusive; however, there is a significantly higher prevalence of stuttering in the developmentally delayed population.

ETIOLOGY

There has been growing agreement among researchers and clinicians that stuttering is a multifactorial disorder. Specifying the level of causation can facilitate understanding the etiology of stuttering.

The first of these levels pertains to underlying causation, which refers to the genetic, neurophysiologic, and psychological factors that may predispose a child to fluency disruption. Research in these areas has been rather cyclic since the 1940s, and various models implicating psychological, learning, and neurophysiologic variables in stuttering have been presented.

One early psychoanalytic theory of stuttering postulated that disrupted speech represents part of the individual’s psychological history, such as disturbed or traumatic early parent–child interaction. Empirical support for this psychoanalytic model is largely lacking, and studies investigating personality factors associated with stuttering have not revealed anything suggesting emotional disturbance or neurosis as a possible cause.

Later psychological models of stuttering have drawn on the principles of classical and operant conditioning to explain stuttering. Several behaviorally oriented researchers offered a model of operant conditioning in which the early dysfluencies of the child were subject to an intermittent schedule of reinforcement, resulting in incipient stuttering. The two-factor theory of stuttering posited that dysfluency resulting from negative emotions becomes associated with speech-related stimuli through a process of pairing, or conditioning, as explained by classical conditioning. The individual’s response to the fluency failure, the repetitions, sound prolongations, and attempts to terminate the instance of disruption are instrumentally conditioned.

Perhaps the best-known psychological theory of stuttering is the diagnosogenic (semantogenic) model as proposed in the 1940s. This theory postulates that stuttering is caused by parents’ diagnoses of the developing child’s normal dysfluencies as stuttering, particularly if the child is also socially sensitive. One of the stronger observations used to support the diagnosogenic theory was that of American Indian tribes of which ones lacking a specific word for stuttering in their tribal language had lower rates of stuttering in their overall population, relative to tribes that did. The underlying fundamentals of this correlation reason that if a child with normal dysfluency is subject to a premature diagnosis of stuttering, they would have a mental block preventing them from realizing their potential. However, there is an understanding that specific vocabulary is not necessary for the sake of communication, which leaves this theory under skepticism as it is still very much possible a child is reprehended and stigmatized for their normal dysfluency.

The large proportion of stuttering individuals who have relatives with a similar speech disorder and the high concordance for stuttering in identical twins have long suggested that biologic inheritance plays some part in stuttering. Current models of genetic transmission that can account for familial patterns of stuttering provide strong evidence for the biologic inheritance of stuttering. Moreover, research utilizing the most current genotyping technologies has confirmed the evidence for a strong genetic factor in stuttering. However, these genetic models point to a complex interaction between heredity and environment. Most recent studies have pointed out several possible specific candidate genes. However, it is too early to declare that specific genes underlying stuttering in the general population have, in fact, been identified. Moreover, at this point in time, it remains unclear as to which specific combinations of motor, linguistic, temperament, or other aspects of speech are being transmitted.

The theory of cerebral dominance, proposed in the late 1920s, was one of the earliest neurophysiologic models used to explain the cause of stuttering. This theory postulated that stuttering resulted from the lack of an appropriately developed hemispheric dominance of speech and language function.

The theory of incomplete or atypical cerebral lateralization for speech has received varying amounts of support, but not until relatively recently did advances in electrophysiologic techniques and brain imaging begin to yield more reliable data on cortical and subcortical processing of speech in stuttering. Much of the earlier research into the nature of these hypothesized brain processes was based largely on the use of behavioral observations and electromyographic measures. Relevant observations included the effects of delayed auditory feedback on the speech fluency of nonstuttering and stuttering speakers, differences in dichotic listening and dual-task interference performance between stuttering and nonstuttering speakers, and articulatory discoordination and oral kinesthetic deficiencies in stuttering individuals. These observations, among others, represented indirect evidence of differences in neural processing between stuttering and nonstuttering individuals.

Most recently, several brain-imaging techniques used to measure regional cerebral blood flow and oxygen consumption have been applied to the investigation of stuttering. Data from these initial studies using single-photon emission computed tomography (SPECT) and positron emission tomography (PET) point to differential activation patterns in stuttering individuals during both oral and silent reading and even immediately after treatment for stuttering. Findings from these studies have reported a general overactivation in several regions of cortical and subcortical motor networks in individuals who stutter. Recent functional imaging studies have reported increased activation in the right frontal-lateral cortex and the medial-anterior cingulate during both silent and oral reading in stuttering individuals. Moreover, the neural activation in stuttering adults is characterized by a generalized bilateral recruitment of cortical and subcortical neural resources involved in both language formulation and speech production, whereas this activation is lateralized for nonstuttering individuals.

Data coming from studies investigating the effects of behavioral treatment seem to suggest that treatment initially results in an increase in recruitment of resources, including cerebellar activity, after an intensive 3-

week treatment period, followed by a significant reduction in the overall amount of activation after 1 year. At the 1-year mark, the overall activation pattern observed in the stuttering speakers is very similar to that observed in the normally fluent speakers. This finding has been interpreted as signaling increased automaticity in the application of learned speech–motor skills.

A recent study attempted to establish whether decreased functional connectivity between speech-related cortical areas was the structural basis for stuttering. The investigation reported that stuttering subjects showed disturbed patterns of activation in the premotor and motor cortices, particularly below the regions that represent the laryngeal and tongue in the left sensorimotor cortex. Further evidence pointing to anomalous anatomical cortical structures in stuttering has been reported in a study using volumetric MRI scans. The study found that anomalous anatomical configurations of perisylvian cortical speech–language areas are more common in adults with stuttering. In addition to several other findings, the authors report that both the right and left planum temporale were significantly larger in the stuttering subjects compared to the controls, and planar asymmetry was reduced, implicating speech and language nonlaterality. The authors point out that the left planum temporale is composed of auditory association cortex, which is important in the higher-order processing of linguistic information and is structurally larger than its homologous counterpart in healthy adults, thus the resulting leftward asymmetry. Researchers have speculated that the left planum temporale may be the neuroanatomical substrate for language, and there is some evidence of a relationship between planar asymmetry and language laterality. Additional structural anomalies have been reported in recent studies examining the neuroanatomical differences in speech-related cortex between stuttering and nonstuttering individuals using voxel-based morphometry. Results revealed significant differences in localized gray and white matter densities of left and right hemisphere regions involved in auditory processing and speech production.

The past decade has seen exponential growth in the number of peer-reviewed articles investigating both functional and structural brain differences in stuttering individuals. While there appears to be much in the way of unclear or conflicting evidence, there have been some consistent findings.

First, several studies have demonstrated that people who stutter demonstrate greater activity in the right hemisphere cortex (gray matter) than nonstuttering individuals. Such overactivation is observed particularly in an area of the right frontal lobe, which is homologous to Broca's area of the left hemisphere. Structural studies have further demonstrated that white matter differences between stuttering and fluent speakers, located primarily in the right primary auditory and frontal cortices, were observed contralateral to the gray matter differences (Fig. 42.4–1). This finding implies that stuttering individuals have decreased functional connectivity between perisylvian areas responsible for hearing speech and producing verbal motor movements, to which the brain tries to overcompensate by contralaterally increasing the formation of white matter tracts. In a recent study of stuttering children, reduced gray matter volumes in the bilateral-inferior frontal gyri and left putamen were observed. These stuttering children also demonstrated increased gray matter volumes in the right ventral premotor and superior-temporal gyri relative to fluent children. These findings are interpreted as reflecting developmental factors resulting in a deficit in speech–motor learning. A number of studies have also reported that stuttering subjects show significantly increased activation in the cerebellum, which is critical for integrating sensory and motor functions early in the acquisition of fine motor skills. In addition, studies have shown decreased corpus callosum tract volume, which communicates information between the right- and left-brain hemispheres, including the finer details of language production, such as tone, humor, irony, and emotions.

A second etiologic level of stuttering involves the precipitating causes—that is, when, where, and under what conditions stuttering is most likely to occur. At this level, the concern is with the loci of stuttering and the specific speaking situations impacting fluency. Linguistic factors associated with stuttering have led some theorists to view it as a higher-level cognitive dysfunction. The vast majority of stuttering occurs on the initial sounds of words or syllables. Fluency-facilitating conditions include choral reading, repeated reading of the same material, whispering, and speaking under conditions of altered auditory feedback or masking noise. Based on these and other phenomenologic features of stuttering, new theories have implicated higher-level linguistic processes as the fundamental causal elements for speech disruption in stuttering. These processes involve the planning or adjustments of linguistic plans via internal monitoring loops. One such theory, the covert repair hypothesis, emphasizes the role of internal monitoring in detecting and correcting phonologic errors in speech planning and production. The theory suggests that the unintended side effects of these elaborate models of internal speech monitoring and repair create internally conflicting conditions, which are, in part, responsible for the dysfluency in both normal and stuttering speech. The brain’s executive section favors the abrupt interruption of normal articulation when there are word-finding or grammatical errors.

A third level of causation and an area of active investigation concerns the motor speech and vocal tract dynamics that are characteristic of stuttering. The vocal tract events generating disrupted speech patterns have been the focal point of much of the physiologic research on stuttering since the early 1980s. It is reasoned that increased knowledge of vocal tract events and the component behaviors of stuttering will ultimately have a direct impact on the diagnostic assessment, measurement, and therapeutic modification of these behaviors. Much information is available on the respiratory, laryngeal, and articulatory dynamics of stuttering. Physiologic studies indicating differences between stutterers and nonstutterers are closely scrutinized because they may, in fact, be dealing only with peripheral events surrounding stuttering, not with underlying causation. The above argument notwithstanding, individuals who stutter, as a group, exhibit relatively longer laryngeal, respiratory, and articulatory reaction times. It has been speculated that the speech–motor systems of people who stutter are limited in their skill or ability to prepare and perform the motor actions that are required to implement the various demands imposed by linguistic, cognitive, emotional, and motor aspects of speech. Additional evidence for this argument comes from within the stuttering patient population, which generally shows boys produce articulations with slower reaction times and diminished amplitude than girls. This observation is upheld by statistical evidence that boys are also five times more likely to be diagnosed with stuttering, providing further evidence that such seemingly peripheral observations may be a potential point of the target for both diagnostic measures and therapeutic modifications such as surgical intervention.

The final level of causation involves the environmental factors associated with the onset and development of stuttering. Much information has been collected on the personality traits of young children who stutter and their parents, as well as the psychodynamic, sociologic, and conditioning factors influencing stuttering and their interaction with linguistic development. Considerable inconsistency exists in data obtained from research on the personality of stutterers. There is little (if any) conclusive evidence that stutterers, as a group, exhibit a definable character structure or predictable set of personality traits. This inconsistency is further evidenced in a series of recent articles investigating temperament, emotional regulation, and emotional reactivity in young children who stutter. Some of these studies suggest that greater emotional reactivity experienced by preschool children who stutter, together with their relative inability to regulate their emotions and control their attention, may lead to fluency breakdown. Other studies have been unable to distinguish between the children who stutter and those who do not on these variables. Moreover, there appears to be much overlap in overall adjustment profiles between stutterers and nonstutterers, with lower social adjustment and self-esteem scores characterizing individuals who stutter. However, these traits are more appropriately explained as a product of affect and personality as opposed to the underlying cause of stuttering itself in these individuals.

DIAGNOSIS AND CLINICAL FEATURES

Stuttering is typically characterized by involuntary disruptions in the fluency of verbal expression. These disruptions may be audible or silent and are usually characterized by repetitions or prolongations of sounds or syllables, tense pauses, or the complete cessation or blocking of speech sounds.

Accessory or secondary features frequently accompany instances of stuttering. These secondary behaviors involve both the speech mechanism and related or unrelated body structures. Such behaviors may include eye blinks, facial grimacing, lip and tongue tremors, tics, vocal fry, head jerks, abnormal movements of the limbs, and breathing irregularities. Linguistic and situational avoidance behavior is often observable with confirmed stuttering. The affected speaker will often scan the intended utterance to predict stuttering and then attempt to avoid such disruption by substituting words, revising phrases, circumlocutions, or stopping the entire communicative process. Situational avoidance is often reported, such as speaking in front of a group or on the telephone. Most adult stutterers report specific sounds, words, or situations that increase stuttering. Most of this information comes from studies carried out on chronic adult stutterers. Children who stutter have not been studied extensively, but it is generally accepted by clinicians that stuttering in its earlier forms is more often restricted to simpler types of dysfluency, such as repetitions and prolongations, and less often involves the more severe struggle and avoidance behaviors. Definitions of *stuttering* vary widely and are usually based on listeners' observations of the disrupted speech pattern. However, some authors emphasize that the affected individual's sensations of the stuttering moment are crucial to any complete definition. Many forms of stuttering are so subtle that they are undetectable by the listener and are only perceived by the speaker.

Although stuttering varies markedly in terms of frequency and severity, both within and among individuals who stutter, some fairly predictable events or situations are commonly observed that either facilitate fluency or result in a deterioration of the stuttering (e.g., choral reading, singing, whispering, speaking in the presence of masking noise or under conditions of delayed auditory feedback, speaking when alone). Conditions commonly observed to increase stuttering include talking on the telephone, talking to groups, making introductions and saying one's own name, talking to authority figures, and attempting to communicate during stressful situations such as job interviews or formal presentations.

Although severe forms of stuttering are most often observed in adults, children and adolescents can be similarly affected. Stuttering can have a significant impact on the individual's quality of life, causing significant social, emotional, educational, and vocational problems. Preschool and young school-aged stutterers frequently develop social and school-related anxiety. In fact, school children who stutter have a sixfold increase in their likelihood of having a diagnosable social or general anxiety disorder, as compared to a nonstuttering child. The adolescent who stutters tends to withdraw from normal social interaction. The young adult stutterer often reports feelings of restricted academic and career choices and often forgoes the opportunity to develop specific talents and career paths.

Adam was a pleasant and likable 8-year-old boy in the second grade. He had a younger brother and older sister whose speech developed normally. Adam's speech was also developing normally until around the age of 3½, at which time he began to show numerous repetitions of words, syllables, and sounds. Adam's pediatrician felt that the dysfluent speech was only a phase that Adam would soon outgrow. Adam's speech progressively worsened, and he began to show signs of struggle as he tried to force his words out on increasingly frequent occasions. The family remained convinced that the physician's predictions would, in fact, be borne out and that Adam would eventually grow out of the problem. By the time Adam was in the second grade, his speech was characterized by severe stuttering, taking the form of silent blocks lasting up to 20 seconds. These blocks were associated with generalized upper body tension and breathing abnormality just prior to the instance of disruption. In addition to being visibly frustrated by his inability to communicate at school and with his friends, Adam became withdrawn and socially isolated. He would not participate in class and would often refuse to go to school if he knew that he would be called on during a certain activity. Adam's mother also reported that there had been several instances of bullying and teasing by two of Adam's classmates. On several occasions, Adam returned home from school crying because of the remarks made concerning his speech. At this point, Adam's mother consented to have the school speech–language pathologist perform a full assessment and begin therapy sessions in order to provide Adam with the relief and support that he had been lacking.

The case study of Adam illustrates two commonly observed scenarios with regard to children's early speech development. First, childhood dysfluent speech patterns are often mistakenly interpreted as normal developmental phenomena. Although it is true that many young children will pass through periods of disrupted speech patterns and will spontaneously recover from these, a significant minority, estimated as high as 30%, of these children will continue to exhibit disrupted speech patterns, and if left unattended, they will develop confirmed stuttering. Recent studies point to the importance of early clinical intervention and, at the very least, referral for assessment by a speech–language pathologist to determine whether treatment is indicated. The case study highlights a second frequently observed social impact on children who stutter: teasing and bullying. Recent studies have demonstrated that more than 80% of children who stutter have, at some point, experienced bullying, usually in the form of teasing or name-calling. Children who stutter will often experience feelings of shame and reduced self-esteem as they are identified by their peers as different and vulnerable. They will often be excluded from their peer group activities and become increasingly withdrawn and socially isolated. Because they feel inadequate as communicators, these feelings of inadequacy quite often evolve into generalized feelings of low self-worth and esteem.

Susan is a 28-year-old bilingual speaker of English and Bengali. At the time of her assessment, her speech was characterized by severe amounts of hard glottal attacks, sound prolongations, and laryngeal blocks. Secondary behaviors observed included eye blinks and lip tremor. She reported that she regularly used avoidance strategies such as starters, fillers, and word switching to avoid stuttering in public whenever possible. Susan also reported that she avoided speaking with unfamiliar listeners and speaking in group situations. Susan reported that she had participated in treatment at the ages of 8 and 10 with some success in structured settings, but her gains had been difficult to maintain.

Based on her assessment, it was recommended that she participate in an adult group intensive treatment program focusing on fluency-shaping strategies. Susan was judged to be an excellent candidate for this model of treatment based on the following criteria: First, she demonstrated through her assessment interview and reading sample that she possessed the intellectual capacity to manage the rigorous demands of the intensive nature of the program. Second, she demonstrated through her oral mechanical examination and trial therapy probe that she was capable of managing the physical demands of altering her motor movement patterns. Third, she evidenced the emotional readiness to benefit from group therapy and to address the cognitive restructuring requirements of the program. Fourth, she evidenced a high level of motivation to successfully complete treatment and participate in a long-term maintenance program.

Susan’s treatment program included 3 weeks of daily clinic sessions lasting for close to 5 hours per day. She further dedicated between 2 and 4 hours to the completion of home assignments each evening.

In addition to successfully acquiring the motor skills required for fluent speech, Susan responded well to the cognitive restructuring goals of the program. She took to heart the suggestion that optimal success in treatment cannot be achieved without a genuine acceptance of one’s self as a person who stutters. She gained a level of comfort and openness about stuttering by completing a number of assignments that required her to practice with a variety of partners outside the group. This afforded her the opportunity to discuss her speech condition and therapy program with a number of family members, friends, and coworkers.

Susan is currently in the maintenance phase of her treatment program. She has taken many positive steps to create a lifestyle that supports her goal of long-term fluency maintenance. Susan carefully completes her daily schedule of maintenance practice. When she neglects her practice, she realizes the negative effect on her speech but manages these ups and downs with a positive attitude. She thoughtfully selects short-term goals at each follow-up meeting that will support her long-term goal of successful maintenance. Most recently, she revealed that she had been accepted to a graduate program in speech–language pathology.

DIFFERENTIAL DIAGNOSIS

The ability to produce fluent speech is a skill that develops as the young child grows, and it depends on such factors as motor coordination, timing, linguistic, and cognitive development, as well as emotional development and maturity. Fluent speech production results when the motor skills to produce a desired message occur sequentially and synchronously in a smooth manner. This requires a fully developed system composed of respiratory, phonatory, resonatory, and articulatory components acting interdependently to produce fluent speech. Given that these systems are not fully developed at 3 or 4 years of age, preschool children quite commonly exhibit dysfluency in speech during their communication efforts. The factors that distinguish normal nonfluency from incipient stuttering involve both the type and frequency of the observed disrupted speech patterns. Children who stutter exhibit predominantly part-word repetitions, voiced or unvoiced sound prolongations, and broken or fragmented words, whereas the normally nonfluent child is more likely to demonstrate whole word and phrase repetitions, revisions, and end syllable prolongations. Several researchers have emphasized the degree of speech fragmentation as the distinguishing factor between stuttering and normal nonfluency. The child who is developing normal speech patterns usually does not evidence more than 10% of any type of dysfluency in speech, whereas the stuttering child often exhibits higher amounts of speech disruption. Another distinguishing factor is the presence or absence of struggle during speech attempts. The stuttering child exhibits difficulty in initiating or maintaining proper breath flow or voicing during speech attempts. The normally developing child is more likely to produce easy, effortless speech with continuous, uninterrupted breathing, even if it is intermittently marked by repetitions of whole words or phrases. As such, a caregiver is in a key position to differentiate whether the child's stuttering requires clinical attention or the child is undergoing a phase of dysfluency.

The discussion thus far has centered on developmental stuttering, the disorder of fluency most commonly observed in children and adults. It should be noted that there are other types of speech dysfluencies that may be observed in clinic populations, two of which will be mentioned here.

Acquired neurogenic stuttering is a condition that can appear for the first time in adulthood and is usually associated with a variety of temporary, progressive, and nonprogressive neurologic disorders, such as traumatic brain injuries, strokes, and extrapyramidal diseases. In addition to adult cases of neurogenic stuttering, there have also been reports in which childhood stuttering worsened or reappeared with the onset of the neurologic disorder. Several features of neurogenic stuttering help to distinguish it from developmental stuttering: general adversities from the problem but no apparent anxiety, instances of dysfluency occurring in any part of the utterance, lack of secondary behavioral symptoms, stuttering on small grammatical words and substantive words with approximately equal frequency, and reduced variability of stuttering across different communicative situations.

Cluttering is another disorder characterized by rapid speech, reduced intelligibility, and frequent telescoping of words under the DSM-5. Cluttering is often marked by grammatical and syntactic errors and is not typically associated with any specific sound or word fears or difficulty maintaining breathing levels when producing sentences. Cluttering has often been associated with a central language imbalance, with some authors suggesting that cluttering exists when an individual presents with one or more impairments in each of five broad communicative dimensions reflecting cognitive, linguistic, pragmatic, speech, and motor abilities. Some of the features differentiating cluttering from stuttering are self-monitoring and general awareness. Whereas people with developmental stuttering are usually hypersensitive to the sound of their own speech, the person who clutters is often only vaguely conscious of their aberrant speech pattern and inconsistencies, let alone the existence of their speech disorder. Cluttering patients are often met with poor prognosis, largely as a consequence of the individual’s denial to seek medical help for a condition they are seldom aware of.

COURSE AND PROGNOSIS

The onset of stuttering can occur anytime between the ages of 2 and 7, peaking at approximately age 4. Most of the risk for the onset of stuttering is usually negated by the age of 6. The stuttering fluctuates in severity initially, as every patient has a unique course of development. Initially, days or weeks may go by with little or no speech difficulty, only to be followed by a sharp increase in the amount and type of stuttering behavior, and this may be dependent on environmental triggers. Despite fluctuations in severity, young children who begin to demonstrate signs of true stuttering do not continue to be dysfluent in the same manner they began. As children begin to demonstrate more struggle and fragmentation of words and syllables, the stuttering pattern becomes more complex. If these children are left unattended, their stuttering episodes slowly become more concrete and chronic, proving more difficult, but still possible, to treat with speech therapy. In its most advanced form, speech disruptions are accompanied by secondary behaviors such as those previously described. Complete recovery from stuttering is rare after puberty. As many as 80% of stuttering children experience spontaneous recovery, with girls more likely to become spontaneously fluent than boys. Investigations of prognosis in therapy for the older, confirmed stutterer have focused primarily on the influence of personality factors in treatment; subjects with less favorable speech attitudes were less likely to obtain long-term benefits from behaviorally oriented speech therapy for stuttering.

TREATMENT

The vast majority of treatment techniques for stuttering have been conducted on adults. Speech–language pathologists have traditionally practiced two distinct forms of therapy. The first deals directly with the psychological and cognitive aspects of the problem—that is, the attitudes, feelings, and emotions displayed by the individual who stutters. Treatment procedures use various types of psychotherapy directed at self-acceptance, attitude change, and avoidance or anxiety reduction. These therapy sessions aim to reduce feelings associated with the triggering of a stuttering episode. The second major speech therapy approach involves modification of the stuttering response to fluent-sounding speech by the application of systematic steps and rules of speech mechanics. In this framework, therapy procedures attempt to reconstruct the respiratory, phonatory, and articulatory gestures used in speech production, either by stuttering modification or fluency-shaping techniques. Therapy formats for adults who stutter have been intensified, and several major stuttering treatment programs now offer full-time treatment approaches administered in blocks of several weeks. Current research and clinical efforts are directed at the maintenance of fluent speech in the posttreatment environment. A significant number of individuals have been reported to exhibit either partial regression or even total relapse of stuttering without the continued practice of speech skills after treatment.

Varying definitions of stuttering and of successful treatment have largely hindered measures of treatment efficacy. Current therapies report success rates ranging from 60% to more than 90% when the sole dependent variable is self-perceived fluent-sounding speech immediately after treatment. However, thorough treatment outcome measures for stuttering should include three elements: (1) a significant positive change in speech output is produced, (2) the change is generalized across speaking situations, and (3) the change is maintained over time.

Far fewer studies have been done on the effects of speech therapy on young stuttering children. Clinicians tend to be somewhat divided on the issue of direct therapeutic intervention for the preschooler who stutters. Many advocate an indirect approach, incorporating parent counseling and environmental manipulation to treat the dysfluent child. This approach incorporates such techniques as parental modeling of relaxed, unhurried speech, and reduction of communicative stressors in the home environment. A second approach trains parents of very young children to apply behavioral techniques of verbal contingencies to stuttering and to verbally reinforce stutter-free speech in the child’s everyday speaking environment. If it is determined that these indirect approaches are not sufficient to fully address the stuttering, direct techniques of speech modification or fluency shaping, such as respiratory control and gentle phonatory onsets, are taught in a manner similar to those used with older populations.

Currently, there are no approved medications for stuttering on the market. However, advancements in neuroscience, such as medications that modify the dopamine receptors that reduce stuttering severity, may give patients a unique treatment option, especially for individuals who are unresponsive to traditional treatment methods.

ACKNOWLEDGMENTS

The chapter was written in memory of the late Dr. Joseph H. Beitchman, who continues to inspire us with his dedication, devotion, and extensive research work in childhood language disorders.

42.5 Unspecified Communication Disorder

TIM BRESSMANN, PH.D.

The section on communication disorders in the current fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders, Text Revision* (DSM-5-TR) focuses on developmental speech and language disorders, which is consistent with previous versions. The category unspecified communication disorder is open ended and may capture other notable aspects of a patient's symptomatology as they relate to verbal communication.

This chapter will focus on voice disorders. Beyond the linguistic information that is conveyed through a speaker's speech, the underlying voice quality can add important information about the speaker's emotional and physical status. The patient's voice quality and quantity can be an important clinical sign in the anamnesis of a range of psychiatric conditions, and psychiatric and voice symptoms can sometimes interface in interesting ways. Voice disorders can equally be an outlet or a cause for stress and emotional turmoil. The boundary between structural and functional (psychological) etiologies is often blurred.

The voice is part of the speech production mechanism. Speech is a complex physiologic phenomenon that relies on the coordination of multiple anatomical systems. Airflow from the lungs causes the vocal folds to vibrate periodically, generating a raw voice that is filtered and shaped in the pharynx. The velopharyngeal sphincter functions like a valve that can direct the airflow orally to produce oral speech sounds. If the velum is lowered, speech sounds will be nasal. The movements of the lips, jaw, and tongue create differentiated, linguistically meaningful speech sounds. Accordingly, the subsystems of speech can be broken down as follows: respiration (airflow from the lungs), phonation (sound generation in the larynx), resonance (shaping of the sound quality in the vocal tract), oral–nasal balance (direction of airflow into the oral or nasal direction at the level of the velopharyngeal sphincter), articulation (modulation of the sound stream into consonant and vowel sounds with the tongue, jaw, and lips), and suprasegmental (speech rhythm, loudness, and intonation).

DEFINITION

In the DSM-5-TR, unspecified communication disorders are described as “presentations in which symptoms characteristic of communication disorder that cause clinically significant distress or impairment in social, occupational, or other important areas of functioning predominate but do not meet the full criteria for communication disorder or for any of the disorders in the neurodevelopmental disorders diagnostic class.” The wording of this descriptor is somewhat unfortunate because it implies that unspecified communication disorders do not reach a threshold of criteria to qualify as proper communication disorders. The DSM-5-TR definition goes on to state that the category is applicable in cases where the clinician chooses not to specify the reason that the criteria for another communication disorder are not met or for situations when there is insufficient information to make a more specific diagnosis.

However, the DSM-5 categories are not comprehensive and detailed enough to capture the full range of communication disorders. While this is reasonable because the DSM-5 focuses on psychiatric conditions, speech–language pathologists may feel that this leaves the manual at an uncomfortable halfway point. Many pediatric communication disorders are included with a fair level of detail, while other important and frequent acquired communication disorders such as aphasia (acquired language disorder), dysarthria (neurogenic motor speech disorder), as well as structurally related speech disorders related to head and neck cancer, to name but a few, are omitted in the DSM-5. The clinician may make a diagnosis of an unspecified communication disorder not because of insufficient information but simply because of a lack of a more appropriate diagnostic category.

Examples of disorders that lend themselves to the diagnosis of unspecified communication disorder include voice disorders but also structurally related disorders such as oncologic pathologies (laryngectomy or glossectomy). Because the latter occur only rarely during childhood and are rather self-evidently related to surgical resections, this section is focused on voice disorders.

Voices are as varied, individual, and recognizable as human faces. What is considered acceptable as normal voice quality, loudness, and pitch may vary markedly between languages or in different cultures. The clinician will therefore try to determine whether a client's voice is appropriate (rather than "normal") with regard to the speaker's physical makeup, culture, and language. A voice may be considered disordered when the speaker experiences marked functional limitations, such as a voice that does not project well or gives out. The vocal quality may attract negative attention and may be perceived as unpleasant by the speaker or the environment. Speaking may be uncomfortable or painful.

HISTORY

The beginnings of modern vocology date to the late 19th century. Much of the research during this time was conducted by singing teachers who were interested in the physiology of the anatomical structures they were trying to educate in their students. The early 20th century saw a rapid improvement in laryngeal imaging methods and a more thorough understanding of the vocal mechanism. During this time, researchers also observed that many voice disorders are the result of chronic hyperfunctional misuse and that the voice can be a target of psychosomatic processes. These findings roughly coincided with the development of early psychoanalysis. As a result, functional voice disorders were often interpreted as a manifestation of a suppressed personal conflict, resulting in a conversion dysphonia. In recent decades, voice scientists and speech–language pathologists have begun to differentiate more carefully between true psychogenic dysphonias and functional voice disorders that are related to excessive muscle tension. Patients with muscle tension dysphonia will experience voice problems chiefly because of poor musculoskeletal alignment. Muscle tension dysphonia can often be treated on its own merit so that a psychodynamic interpretation of the disorder is no longer regarded as necessary or helpful in every case.

COMPARATIVE NOSOLOGY

Human communication disorders are as complex and as varied as psychiatric conditions. The DSM-5 continues to recognize the relevance of communication disorders to the psychiatric profession. However, it is neither the aim nor the scope of the DSM-5 to provide the level of detail and differentiation that a speech–language pathologist would bring to the diagnosis and treatment of communication disorders. There are manifold communication disorders that cannot meet the relatively narrow criteria for the types of developmental communication disorders laid out by the DSM-5. Consequently, the DSM-5 category unspecified communication disorder is a diagnostic wild card.

EPIDEMIOLOGY

There are few reliable epidemiologic estimates for the prevalence of voice disorders, and the available figures vary considerably between studies. In part, this is due to uncertainty about the concept of the healthy voice: The acceptability of different vocal qualities and quantities varies considerably in different cultures, languages, and on different socioeconomic levels. Voice quality is an auditory–perceptual impression, so what is considered to be typical or pathologic is very much in the ear of the beholder. The estimated prevalence for pediatric voice disorders ranges from 6% to 23%. The prevalence of adult voice disorders has been estimated between 3% and 10%. The available epidemiologic reports vary in group sizes and compositions as well as in methodology. It is also difficult to estimate how many of the speakers who have been identified as having a pathologic voice quality will require treatment. The need for behavioral, surgical, or pharmaceutical intervention can probably be estimated to be closer to the lower, more conservative end of the prevalence estimates.

The occurrence of voice disorders varies across the lifespan. In children, boys tend to have more voice disorders, probably due to more aggressive vocal behavior and boisterous vocal play. By adolescence, the prevalence is roughly balanced between the sexes. In adults, voice disorders are more frequent among men than women. However, women seek help more often and sooner than men. The highest prevalence of voice disorders in adults is found in the age group of 45 to 64 years. Overall, most voice disorders are benign in nature (vocal nodules, polyps, edemas, and functional dysphonias).

ETIOLOGY

The precise etiology of a voice disorder is often difficult to determine and needs to be evaluated based on the nature of the pathology, the patterns of voice use, the emotional and physical states, and the underlying or accompanying medical conditions of the individual patient. Sudden onsets tend to denote acute processes, which are mostly reversible, and slow progressive onsets tend to denote longer-standing vocal trauma or degeneration that may require more comprehensive behavioral interventions, often in combination with phonosurgery.

Voice disorders are characterized by deterioration in vocal quality and quantity. A lesion on the free margin of the vocal fold results in incomplete vocal fold closure and a breathy, rough, or hoarse voice quality with a decreased loudness and pitch range. A referral to the otolaryngologist is necessary if a persistent change in vocal quality and quantity is observed. The otolaryngologic examination should always comprise a visual inspection of the larynx in order to rule out potential malignant lesions, such as squamous cell carcinoma.

Voice disorders can be congenital or acquired. The relatively rare congenital disorders of the larynx include conditions such as laryngomalacia (softness of the cartilages of the larynx and the epiglottis), subglottal stenosis (laryngeal webbing between the vocal folds), and rare laryngeal clefts. The immediate concern in infants with these pathologies is to keep the airway patent and ensure the patient can breathe.

Most voice disorders are acquired. Acquired voice disorders present as a hen-or-egg problem: It is difficult to determine whether abusive vocal behavior has led to a vocal pathology or whether a pre-existing pathology has triggered a vicious cycle of maladaptive behavior. Consequently, voice therapy and vocal re-education are paramount in all vocal pathologies.

In both children and adolescents, acquired voice disorders can be caused by a number of factors. The most important factor that causes injury to the vocal folds is vocal misuse (vocal hyperfunction) through excessive yelling, singing, talking, aggressive vocal play, or abusive body-focused repetitive behaviors such as excessive throat clearing. Voice disorders related to vocal misuse are often labeled as hyperfunctional voice disorders. Acute and traumatic vocal misuse can lead to lesions in the vocal fold, such as acute inflammatory (usually bilateral) vocal nodules, acute vocal fold polyps, or acute vocal hemorrhage. If these conditions are the consequence of a singular event (e.g., a spectator sports event), they are usually easily reversible by vocal rest and vocal hygiene. Protracted vocal misuse may require more comprehensive behavioral and possibly surgical interventions.

Long-standing voice misuse may result in chronic, fibrotic vocal nodules or chronic, indurated polyps. The delicate and supple superficial layer of the vocal fold (Reinke space) is particularly prone to irritation and swelling, resulting in chronic inflammatory edema of the vocal folds (Reinke edema, chronic laryngitis, polypoid degeneration). Granulomas or contact ulcers on the arytenoid cartilages may be a consequence of low-pitched, strained phonation, sometimes in combination with gastroesophageal reflux. Many of these pathologies will be accompanied by excessive muscle tension, which is often visible and palpable in the extrinsic strap muscles of the larynx. This tension leads to an elevated position of the larynx during phonation. Muscle tension dysphonia can be a symptom that accompanies an organic pathology, or it can be a voice disorder by itself.

Excessive muscle tension is also often found in psychogenic dysphonias. Patients with psychogenic voice disorders can present with severe dysphonia or even complete aphonia (loss of voice), although the larynx is free of any visible pathology. The symptoms of psychogenic dysphonias can be variable: Patients may claim a total loss of voice and present with only whispered or breathy phonation or they may present with an excessively rough and hoarse voice quality, often accompanied by pain and discomfort when speaking. In some psychogenic dysphonias, the ventricular folds (false folds) are adducted together with the true vocal folds. The ventricular folds are situated above the true vocal folds. This mixed glottal–ventricular phonation can be visualized endoscopically and results in rough, low-pitched voice quality (comparable to the singing technique used by Louis Armstrong). The onset of psychogenic dysphonias is mostly sudden, sometimes related to a bout of cold or laryngitis in combination with a high level of life stress or emotional upheaval. According to reports, patients with psychogenic dysphonias are predominantly female, but men and children may also be affected.

A specific psychogenic dysphonia that begins in adolescence (but sometimes extends into adulthood if left untreated) is puberphonia, in which the prepuberty pitch and voice quality are retained by the patient. The result is an age-inappropriate high-pitched voice. It is more obvious in men than in women since the male voice drops about an octave (12 semitones) in puberty, compared with about a terce (3 semitones) in females. A puberphonic voice disorder is called postmutational falsetto in men and juvenile voice in women. It is idiopathic but may be associated with resistance to adolescence and adulthood or a feminine self-identification (in men). It is often possible to elicit a more physiologic pitch from these speakers during nonspeech maneuvers such as coughing, throat clearing, and laughing. The discrepancy between the pitch of the speaking voice and during nonspeech tasks can be an indicator of psychogenic dysphonia or of postmutational falsetto.

The complete refusal to vocalize or speak is called selective mutism. This disorder is predominately observed in younger children. These children first achieve the regular milestones in speech and language development but, at some point, refuse to speak because of emotional or psychosocial distress. Most children with selective mutism limit their interaction to a small number of immediate family members with whom they have close relationships. The incidence of prolonged mutism (i.e., longer than 6 months) has been estimated at less than 1 child in 1,000. Girls are more prone to this disorder than boys. The DSM-5 classifies selective mutism as an anxiety disorder.

A disorder that is difficult to categorize in children as well as in adults is idiopathic paradoxical vocal fold movement. This disorder also goes by vocal cord dysfunction or exercise-induced laryngeal obstruction. Patients with this disorder are still frequently misdiagnosed with either asthma or with a panic disorder. The patients experience spontaneous respiratory distress, often related to strenuous physical activity, in a fashion that is similar to an asthma attack. However, no swelling of the bronchi and the trachea occurs in an episode of idiopathic vocal fold movement. The patient experiences isolated involuntary laryngospasms, resulting in complete closure of the vocal folds. Consequently, asthma medication will not provide the necessary relief. Instead, this disorder responds well to behavioral therapy and specific breathing exercises to open the vocal folds.

Viral infection with the human papillomavirus can affect the respiratory tract in children and adults and lead to multiple lesions. In order to prevent the spreading of papillomatosis into the trachea and lungs, the lesions are surgically removed. Since papilloma lesions tend to recur, multiple rounds of surgery may be required. Although this treatment is effective for viral infection, it may result in severe scarring of the larynx and the vocal folds. An incomplete or irregular vocal fold closure with a hoarse and breathy voice may result. While this condition is initially organic, the disease and its often-lengthy course of treatment can have significant downstream effects on the patient's psychosocial well-being and quality of life.

Neurogenic voice disorders are related to lesions or degenerative processes in the nervous system. Peripheral vocal fold paralysis can be caused by strokes, degenerative disorders, mechanical or surgical trauma, or viral infections. The peripheral paralysis can be uni- or bilateral, and the location of the lesion along the nerve will determine the position of the affected vocal fold and the consequences for breathing, swallowing, and speech. Lesions in the central nervous system have a more generalized impact on the whole speech motor system on all levels: respiration, phonation, resonance, articulation, and prosody. Depending on the localization of the lesion along the central motor pathways, a spastic, hyperkinetic, hypokinetic, ataxic, or pseudobulbar movement disorder will result. The associated motor speech disorders are labeled accordingly (as spastic, hyperkinetic, and so forth dysarthrias) and are thought to roughly reflect the nature of the underlying movement disorder. Apraxia of speech is a motor speech disorder that is characterized by deficits in muscle coordination and sequencing of speech gestures. This also affects the coordination of the laryngeal voicing and devoicing for voiced and unvoiced speech sounds (e.g., to differentiate /f/ and /v/).

Spasmodic dysphonia is an insidious neurogenic voice disorder that is believed to be a focal dystonia (like torticollis or blepharospasm), possibly caused by small lesions in the basal ganglia. In spasmodic dysphonia, phonation is interrupted by adductor (adductor spasmodic dysphonia) or abductor spasms (abductor spasmodic dysphonia). The voice quality in spasmodic dysphonia is unsteady and often effortful, marked by a chaotic pattern of vocal fold adduction and abduction. Visceral voice production during coughing or throat clearing is often unimpaired. However, during conscious, purposeful speech, the spasms become obvious. Spasmodic dysphonia is very rare in children and adolescents, but occasional cases have been reported. Diagnostically, it can be a challenge to differentiate spasmodic dysphonia from other disorders, such as psychogenic dysphonia or idiopathic paradoxical vocal fold motion.

A number of factors may aggravate or precipitate voice disorders, such as insufficient hydration, other medications, and gastroesophageal reflux. The vocal folds can be dehydrated by insufficient intake of fluids, active and passive smoking, or exposure to irritating or toxic chemical fumes in the work or home environment. Severe dehydration makes the vocal folds less flexible and more vulnerable to mechanical trauma caused by loud singing, shouting, aggressive throat clearing, and so forth. Medications can also contribute to vocal fold dehydration. Bronchodilators can influence airflow and air passage. Diuretics, corticosteroids, and decongestants can reduce the fluid level in the vocal fold. Antihistamines, antitussives, and antirefluxiva can reduce pharyngeal and laryngeal secretions. Long-term hormonal therapies (especially with testosterone) can change the vocal fold structure and permanently lower the pitch. A number of psychotropic drugs can cause xerostomia and have dehydrating effects on the vocal folds, including tetracyclic, tricyclic, antipsychotic, and anxiolytic drugs. Usually, the level of oral secretions is a good predictor of the laryngeal secretions and the lubrication of the vocal folds. If marked xerostomia is observed, the patient should be counseled about hydration by a speech–language pathologist before they develop voice problems. Finally, acid reflux from the esophagus can lead to esophagitis (gastroesophageal reflux disease, GERD) with ulcerations or granulomas on the posterior aspect of the vocal folds or the arytenoid cartilages and a resulting voice disorder. Reflux esophagitis with irritation of the larynx may also be the result of self-induced vomiting in bulimic patients. While the most acute symptoms of gastroesophageal reflux are typically observed at night when the patient is lying flat, a subgroup of patients with voice disorders report voice symptoms and pain while awake and upright. A common descriptor for this variety of reflux is laryngopharyngeal reflux.

The perceived subjective impairment resulting from a voice disorder is highly variable across patients. In the extreme, voice disorders may cause anxiety and depression and may impact the patient’s work and social interactions. Anxiety about the restitution of the premorbid voice quality is usually highest among professional voice users, such as singers and actors. Professional voice users are often very emotional about even minor changes in their vocal quality and range. Voice problems in professional voice users may sometimes be related to unrealistic or unhealthy artistic demands on the voice, such as prolonged singing or shouting with a deliberately rough and loud voice. In this sense, the vocal folds of a professional voice user are like the knees of a professional basketball player: Irrespective of talent, the body has individual physiologic limits for every organ. Some rock music singers have seemingly endless vocal stamina and never sustain a vocal injury, even though they misuse their vocal folds every night on stage. Other singers hit the physiologic limits of their larynx a lot sooner, despite a correct singing technique.

A population with unique voice therapy needs is transgender patients who strive to adjust their voice quality and speech. For the transgender patient's satisfaction with the treatment outcomes and quality of life, the voice change can be more relevant than the physical appearance. Therefore, it is important to ensure that the patient is referred to a speech–language pathologist who is competent in voice therapy for this group. In female-to-male transgender patients, male hormone therapy will lead to a thickening of the vocal folds, which will lower the speaking pitch. However, the vocal tract size will still be female, and the patient may have to work with a speech–language pathologist on developing masculine speaking mannerisms. The transition is often more difficult for a male-to-female transgender patient. The patient must learn to raise the speaking pitch and develop more feminine speaking habits. The larger male vocal tract size can make it more difficult for male-to-female transgender patients to project a female vocal image. Transgender patients can differ in their ambitions as well as their abilities to change their vocal gender as perceived by others, so the patient and the speech–language pathologist have to establish the most efficient strategies to achieve a voice quality that will be comfortable for the patient and effective for their social speech communication.

A final etiology that needs to be mentioned in this section is velocardiofacial syndrome (22q11 microdeletion syndrome). This congenital syndrome is related to a microdeletion on the long arm of chromosome 22 and has highly variable symptoms. As a result, patients are sometimes not identified at birth but only later when symptoms become manifest. Many of the patients show various developmental delays, especially with regard to speech and language development. In childhood, attention deficit hyperactivity disorder, anxiety disorders, phobias, or emotion regulation disorders are considerably more frequent than in the general population. In adulthood, schizophrenia and schizoaffective disorders are frequently observed. As part of the syndrome, many patients present with cleft palate, which leads to hypernasality (too much air and sound emitted through the nose during speech). The cleft palate in this population is often isolated so that it does not affect the lip and the alveolar ridge and is not visible in the patient’s face. It may even be submucous (concealed under a lining of mucosa) and hidden from a casual oral inspection. Patients with velocardiofacial syndrome are a prime example of the importance of interdisciplinary treatment of complex disorders. The members of the craniofacial treatment team need to be aware of the patient’s risk for mental health problems during their lifespan. On the other hand, a psychiatrist who notices hypernasal speech in a patient who has not been followed by a craniofacial team should make the appropriate referral.

DIAGNOSIS AND CLINICAL FEATURES

Any unexplained change in voice quality, especially when it involves hoarseness or pain and persists longer than 2 weeks, should be examined by an otolaryngologist. The diagnosis of voice disorders is based on several diagnostic procedures. One important component is the perceptual evaluation of the voice disorder by an experienced otolaryngologist or speech–language pathologist. This evaluation assesses the patient’s voice quality and quantity. Accepted general descriptors of voice quality are breathiness (resulting from incomplete closure or hypoadduction of the vocal folds) and roughness (irregular vocal fold vibration resulting from lesions on the vocal fold or hyperadduction of the vocal folds). Hoarseness is defined as a mixture of roughness and breathiness. Vocal quantity can be described in terms of the pitch and dynamic range of the voice. If the pitch is inappropriate, a speaker’s voice is too high or too low for their age, maturation, and sex. If the dynamic range is inappropriate, a patient may speak too loudly or too softly or may have difficulties raising their voice. Associated perceptual assessments concern the patient’s oral–nasal balance, which may make speech sound hyper- or hyponasal or may add a nasal twang quality. It should be noted that hyper- or hyponasality are not voice disorders per se. Finally, suprasegmental features of speech (prosody, speech melody) are assessed. Pathologic prosodic patterns include monotonous, unmodulated voice versus exaggerated inflections, excessively slow or fast speech, and inappropriate or uneconomical breaks for inhalation during speech. Quantitative instrumental measures of voice quality, voice range, or airflow can supplement the perceptual diagnosis. This is combined with a detailed interview that assesses voice usage and medical history together with health practices, social and occupational circumstances, and psychological well-being. In pediatric patients, developmental and family information need to be considered.

PATHOLOGY AND LABORATORY EXAMINATION

Most lesions of the vocal folds are benign and do not require detailed histologic analysis. However, suspicious lesions should be biopsied and analyzed in order to rule out malignancies. The malignant laryngeal tumors are usually of the squamous cell carcinoma type. Irrespective of the clinical presentation of the voice disorder, the vocal folds should always be examined visually by an experienced otolaryngologist in order to correctly assess or rule out any organic causes of the problem. This can be done with a simple mirror examination, but ideally, a flexible endoscopy or a videostroboscopy should be performed. The videostroboscopic examination allows the physician to slow down the display of the vocal fold motion so that the patterns of vocal fold vibration can be observed. High-speed video kymography allows filming the vocal fold motion in real time, with a temporal resolution of several thousand exposures per second. Although a complete and comprehensive assessment of a patient’s vocal structures can be crucial to determining the correct treatment, otolaryngologists may sometimes contend with only superficial investigations, especially of pediatric clients. Malignancies of the pediatric larynx are extremely rare, while on the other hand, a videostroboscopic examination of a small child can be very tedious. However, this wait-and-see attitude may sometimes delay appropriate treatment. Voice disorders in pediatric and adolescent populations should be taken just as seriously as adult voice disorders.

DIFFERENTIAL DIAGNOSIS

Today, most voice centers use videostroboscopy or flexible endoscopy. With these methods, organic voice disorders can be readily detected. However, the challenge in voice diagnosis is to identify the behavioral components of the voice disorder. In particular, the differential diagnosis between hyperfunctional voice disorders and psychogenic voice disorders can often be difficult for otolaryngologists and speech–language pathologists. As a result, the necessary referral to psychiatric services may be delayed. Psychogenic voice disorders often have a characteristic onset. They come about suddenly, sometimes related to a minor viral infection. The discrepancy between visceral vocalizations, such as yawning, and voice production in speech is often informative. If a normal voice quality can be produced during coughing, throat clearing, humming, yawning, and sighing but not in speech, then it is likely that the patient can be helped back to a normal voice by a short course of voice therapy. After an acceptable voice quality has been restored, the patient should be referred for a psychiatric follow-up. On the other hand, if the patient presents with a total loss of voice but does not cooperate with the therapist’s efforts to restore voice production, a different disorder to consider in pediatric patients is selective mutism.

One of the most difficult diagnoses for an otolaryngologist or a speech–language pathologist is spasmodic dysphonia, which is often diagnosed by exclusion of other applicable pathologies. In particular, psychogenic and neurogenic voice disorders must be ruled out. Since not every clinician is aware of spasmodic dysphonia, some patients still undergo prolonged diagnostic and therapeutic odysseys before the correct diagnosis is finally made. The voice breaks in spasmodic dysphonia may sometimes resemble the tonic blocks of a person who stutters. While the onset of spasmodic dysphonia is in adulthood, stuttering begins during childhood. Another difficult diagnosis is that of idiopathic paradoxical vocal fold motion, which can very much resemble an asthmatic attack. However, the airway constriction in these patients will be restricted to the level of the larynx and will not include the bronchi and the trachea. Finally, patients with velocardiofacial (22q11 microdeletion) syndrome may often present with hypernasality as well as a variety of psychiatric disorders throughout their lifespan. Therefore, it is important to ensure that any psychiatric patient with hypernasality of unclear etiology is referred to a craniofacial team for multidisciplinary assessment and genetic testing.

COURSE AND PROGNOSIS

As voice disorders may be caused by many different conditions, there is a high degree of variability in the long-term prognoses and treatment success. Acute organic processes that are associated with a one-time event of vocal trauma usually have a good prognosis. Examples of such pathologies are acute nodules or polyps. Vocal nodules in children are sometimes not removed by surgery as the vocal fold expands during puberty, and the nodules tend to resolve spontaneously. Organic pathologies that are related to long-standing vocal misuse will require more comprehensive therapeutic interventions that also address the associated abusive behaviors. Examples of such pathologies are chronic nodules, chronic polyps, and Reinke edema. If there is persistent voice misuse combined with aggravating factors such as smoking or alcohol abuse, the long-term prognosis can be poorer. Lesions such as nodules may recur quickly after a surgical resection if the maladaptive behaviors cannot be modified. Voice disorders with a pronounced psychogenic component should be addressed with a combined effort by the speech–language pathologist and the psychiatrist. Although the voice disorder can usually be managed effectively in speech therapy, the underlying emotional or psychosocial factors that have contributed to the voice disorder have to be evaluated by a psychiatrist.

TREATMENT

Intervention in voice disorders is dependent on the nature of the problem. Organic pathologies are often managed surgically with laser surgery or microsurgery, followed by a course of voice therapy. In functional voice disorders, the speech–language pathologist will counsel the patient about the nature of the disorder and commence a course of vocal re-education aimed at modifying or eliminating vocal misuse. If psychological factors contribute to the genesis or the persistence of the voice disorder, a referral to psychiatric services will be necessary.

There are many different approaches to voice therapy. Most of these fall within five main streams of voice therapy: symptomatic, physiologic, psychogenic, hygienic, and holistic. This distinction is largely academic because the boundaries between the different approaches are blurred. Most voice therapists will move between these different schools of thought and pursue a more personal eclectic approach to achieve optimum outcomes for their patients. *Symptomatic* voice therapy uses interventions and voice exercises that are geared toward the voice symptoms of the individual patient. *Physiologic* voice therapy draws on concepts from physical therapy, such as respiration or posture exercises, to achieve the foundations for physiologic voice production. *Psychogenic* approaches to voice therapy draw on the cognitive behavioral approach to behavior modification to change the way in which a patient reacts to life stresses with a change in voice quality. This type of therapy also uses relaxation techniques such as progressive muscle relaxation. *Hygienic* voice therapy is often a supplement rather than a standalone therapy approach. Hygienic voice therapy emphasizes proper hydration and reduction of gastroesophageal reflux. Finally, a number of schools of voice therapy are *holistic* in that they try to achieve goals on multiple levels through a fixed program of exercises. To give just a few examples of such holistic approaches, the *vocal function exercises* treat the vocal muscles like other muscles in the body and provide consist of endurance and stretching exercises to increase the vocal range and stamina. The *accent method* uses a combination of controlled respiration, chanting, and dancing to elicit relaxed phonation. *Resonant voice therapy* aims at maximizing oral resonance and achieving good voice projection through a combined program of vocalizing and increasing self-awareness.

The voice can be an outlet for psychological stress. While everybody has experienced symptoms such as a shaky voice or a dry mouth when feeling excited or threatened, in some patients with psychogenic voice disorders, more significant somatoform symptoms such as throat pain and globus sensation can occur together with a change in voice quality. These patients need help to find their normal voice again and often require a referral to psychiatric or counseling services to address the issues underlying the psychogenic voice disorder.

On the other hand, it is also easily possible to conjure up voice symptoms with the purpose of malingering. Garth was a boy of 8 years of age with typical speech and language. When the family moved to a new neighborhood, Garth initially found it difficult to settle into his new school. It was during this time that he came down with frequent bouts of throat pain, accompanied by coughing and alarmingly rough and hoarse voice quality. When these episodes occurred, he could stay home and rest. Because of the recurrent and worrisome voice symptoms, the family met with the school speech–language pathologist when Garth was going through another bout. The speech–language pathologist made Garth laugh with a joke and tested a few nonspeech vocalizations, such as yawning and sighing. On all of these nonspeech vocalizations, voice quality was regular. During the conversation, it also became clear that there was a pattern where the throat pain and voice symptoms became worse around the middle of the week but then improved toward the weekend when Garth was able to participate in family activities again. The patient was confronted with this pattern and agreed that he might have overstated the severity of the pain and voice symptoms. After a few sessions with a psychotherapist specializing in pediatrics and with the support of his family, Garth transitioned smoothly into his new school environment.

Steven was a 17-year-old teenager who was referred to the speech–language pathologist because of his high-pitched voice. Steven had experienced teasing and negative comments about his voice in the classroom and in other social situations. He was very motivated to change the pitch of his voice. The patient was of normal height and built for his age. An otolaryngologic mirror examination had ruled out the presence of a vocal fold web (patients with a laryngeal web often have a high pitch because the vibrating edge of their vocal folds is shorter). Upon palpation, the larynx was normal in size and had a normal movement range when Steven was asked to swallow (laryngeal elevation) and yawn (laryngeal lowering). An acoustic measurement revealed a fundamental frequency of around 230 Hz, which was twice as high as the appropriate pitch for a male speaker. When the patient was asked to throat clear and to hum, the fundamental frequency dropped to an appropriate range. The speech–language pathologist used gentle vocalization exercises such as chanting in combination with manual circumlaryngeal massage in order to help the patient relax his larynx and lower his fundamental frequency. Steven required only six sessions with the speech–language pathologist to change the pitch of his voice. However, he was apprehensive about using the new voice with his classmates at school. He was worried that the change was quite startling and that he would be ridiculed for seeing a speech–language pathologist. Steven decided that he would spend the Christmas holidays with his family and avoid seeing his friends during these days. When he went back to school in the new year, he told his classmates that he had been sick with flu and that the associated cough had done some damage to his voice box, which had changed his voice.

The patient described here was very motivated to change his voice to an age-appropriate pitch. However, some patients may initially resist the speech–language pathologist's efforts. Speaking with a different fundamental frequency changes a physical activity that is deeply ingrained, and that is as difficult to change as one's posture or gait. Patients may sometimes complain that the new way of phonating feels uncomfortable, hurts their larynx, or even affects their breathing. These initial complaints are usually overcome, and postmutational falsetto should be resolved with a short course of voice therapy. The effect on the patient's appearance in social situations can be stark, so it is important to help the patient develop strategies to gently introduce the environment to the new voice.

In puberty, the male larynx grows, and the fundamental frequency drops by an octave or 12 semitones. By contrast, the female larynx shows less growth, and the fundamental female frequency only drops three to four semitones. This means that female puberphonia (also called juvenile voice) can be less obvious and more difficult to recognize than the postmutational falsetto of male speakers. As a result, female puberphonia may be overlooked and treatment delayed.

Autism Spectrum Disorders

Fred R. Volkmar, M.D., Giacomo Vivanti, Ph.D., Ryan K. C. Yuen, Ph.D., and Kevin Pelphrey, Ph.D.

OVERVIEW

The spectrum of autism is characterized by severe and persistent problems in social interaction and difficulties with change and unusual responses to the environment consistent with the first description of the condition by Leo Kanner in 1943 (Kanner, 1943). In DSM-5, the term for the prototypic disorder is changed to autism spectrum disorder (ASD), reflecting an awareness of the broader range of difficulties observed. This term is meant to correspond (roughly) to the earlier diagnosis of autistic disorder in DSM-IV, although as discussed subsequently, the concept is somewhat narrower (despite the spectrum name). DSM-5 also includes a new communication disorder—social communication disorder—to encompass problems in social (pragmatic language) communication.

DEFINITION

ASD now encompasses, to varying degrees, the various concepts previously recognized in DSM-IV as part of the overarching pervasive developmental disorder category. In DSM-5, the historically used triad of impairments in social interaction, communication, and repetitive and restricted interests/behaviors was collapsed into two domains: social communication and restricted and repetitive behaviors. The definition requires that all four of the social communication criteria be met (see Table 43–1) and at least two of the four restricted interests and repetitive behaviors must be met. Sensory problems are now included in the latter group. These difficulties must be present from early childhood. Given the significant concern that this approach excludes many of the individuals who would have had a diagnosis of some pervasive developmental disorder in DSM-IV, a specific exception is made so that individuals with "well-established" diagnoses of Asperger disorder or pervasive developmental disorder not otherwise specified (PDD-NOS) can keep their label (and thus not be excluded from services). Effectively this solution continues the older DSM-IV system for previously diagnosed cases while creating a new (and somewhat different) one for newly diagnosed cases.

The DSM-5 also provides a series of specifiers, for example, if a known etiologic factor is present. Another change is the inclusion of a descriptor of required levels of support (this is left relatively ambiguous), with a range from levels 1 to 3. Other specifiers can indicate association with intellectual disability and language impairment or catatonia (see Table 43–2).

The changes in DSM-5 have been somewhat controversial. The older DSM-IV system used 12 polythetic criteria grouped in the three traditional areas (impairments in social interaction, communication, and restricted/repetitive interests) and resulted in over 2,000 combinations of criteria that could yield an autism diagnosis while the current approach offers only 12 such possibilities. A substantial body of work now makes it clear that, likely as a result of the way the DSM-5 system was developed, it takes a narrower view of autism. The two groups (in DSM-IV terms) who are at greatest risk of losing a diagnosis are the higher cognitively functioning and the more able younger children. Perhaps 80% of the higher cognitively functioning cases that previously would have had diagnoses of Asperger's or PDD-NOS lose their diagnosis with DSM-5, as do a significant number of more able individuals who previously would have had a diagnosis of autistic disorder.

The more stringent DSM-5 approach basically reflects the fundamental source of the data used, that is, high-quality data from research diagnostic instruments designed to assure consistency in autism diagnosis for cross-site genetic studies. The rationale for the new social communication disorder (a communication disorder diagnosis) is murky and the condition does not simply correspond to the older DSM-IV labels of Asperger's or PDD-NOS. The utility of the various proposed modifiers is debated with concern over their reliability given that clinical presentation can dramatically differ depending on observational context.

HISTORY

The first report of autism as a syndrome was provided by Leo Kanner in 1943. He described 11 children who had what he termed autistic disturbances of affective contact. He felt that this difficulty was innate and viewed this, along with insistence on sameness and difficulties with change, as the two essential features of the condition. Kanner noted the stereotyped motor mannerisms of autism and suggested that these were part of the child's difficulties with change and preference for sameness. Although he did not regard communication skill deficits as essential, he did observe that many of his cases never talked, and those who did have speech that was unusual for echolalia (repetitive use of phrases), unusual voice quality and volume, pronoun problems, and general difficulties in social use of language (pragmatics).

In giving autism a greater historical context, it should be noted that cases of autism had been noted before Kanner's report, for example, possible reports of some "feral" children as well as case reports from state training schools in the United States in the 1800s. His description also gave some false leads relative to confusion of the condition with schizophrenia (the use of the word autism—previously used to describe self-centered thinking in schizophrenia), a lack of apparent associated medical conditions, a tendency for parents to be well educated and successful, and the impression that the children did not have associated intellectual disability, given that on some of the nonverbal parts of IQ tests they did well. Even with these caveats, however, Kanner's phenomenologically based description remains classic.

A year after Kanner's report, Hans Asperger, a Viennese medical student, reported on a group of boys with a condition he termed "autistichen psychopathen" (probably best translated as autistic personality disorder). This group of boys had major social difficulties (hence the word autism as also used by Kanner) but good verbal language abilities, remarkable circumscribed interests that were all encompassing, and motor difficulties. The latter features were an area of difference from Kanner's description. Over time, the validity of the concept he described has been much debated and, although DSM-5 has no longer included it, the previous recognition in DSM-IV led to considerable public awareness and interest and an increase in research. In some ways, one of the most significant aspects of Asperger's work was to make it clear that there was a broader spectrum of autism—that is, consistent with the name change in DSM-5 if not with the definition used. His emphasis on genetic factors (he mentioned that fathers had similar problems) also prefigured the considerable interest in genetics discussed subsequently. Indeed, the recognition of a "broader autism phenotype" (BAP) has been the focus of much interest.

Table 43–1.
Autism Spectrum Disorder

Diagnostic Criteria

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive, see text):
   1. Deficits in social–emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.
   2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.
   3. Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.

Specify current severity:

Severity is based on social communication impairments and restricted repetitive patterns of behavior (see Table 43–2).

B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples are illustrative, not exhaustive; see text):
   1. Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypies, lining up toys or flipping objects, echolalia, idiosyncratic phrases).
   2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns or verbal–nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat food every day).
   3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with

unusual objects, excessively circumscribed or perseverative interest).

4. Hyper- or hyporeactivity to sensory input or unusual interests in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior (see Table 43–2).

C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).

D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.

E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.

Note: Individuals with a well-established DSM-IV diagnosis of autistic disorder, Asperger disorder, or pervasive developmental disorder not otherwise specified should be given the diagnosis of autism spectrum disorder. Individuals who have marked deficits in social communication, but whose symptoms do not otherwise meet criteria for autism spectrum disorder, should be evaluated for social (pragmatic) communication disorder.

Specify if:

With or without accompanying intellectual impairment

With or without accompanying language impairment

Associated with a known medical or genetic condition or environmental factor (Coding note: Use additional code to identify the associated medical or genetic condition.)

Associated with another neurodevelopmental, mental, or behavioral disorder (**Coding note:** Use additional code[s] to identify the associated neurodevelopmental, mental, or behavioral disorder[s].)

With catatonia (refer to the criteria for catatonia associated with another mental disorder, for definition) (**Coding note:** Use additional code 293.89 [F06.1] catatonia associated with autism spectrum disorder to indicate the presence of the comorbid catatonia.)

In the years following its first definition, work on autism was limited and hampered by diagnostic confusion. This began to clear as diagnostic guidelines were suggested, as some of the misconceptions of autism were clarified (e.g., that autism could be associated with intellectual deficiency, was seen in all social classes, and was associated with a number of medical conditions, including epilepsy and some genetic conditions). During the 1970s, several lines of evidence converged to show that autism was a strongly genetic and brain-based disorder that responded best to structured teaching. Autism was first recognized officially in 1980 in DSM-III, and research both on biology and treatment expanded dramatically with this recognition.

COMPARATIVE NOSOLOGY

Before DSM-III, autism was regarded as a form of childhood schizophrenia, but during the 1970s, the work of Kolvin, Rutter, and others made it clear that these were actually two very different conditions. This recognition, along with other evidence on the validity of autism, led to its official recognition in DSM-III in 1980. The DSM-III definition was monothetic and heavily influenced by the work of Rutter but unfortunately lacked a developmental orientation (the condition was termed and defined as “infantile autism,” and cases not meeting the strict criteria given, but who once had done so, received a diagnosis of “residual infantile autism”—even though their problems were not particularly residual). In DSM-III-R, a more developmentally polythetic definition of autistic disorder was proposed based, in part, on the work of Lorna Wing. It did a better job in covering the entire range (in age and levels of severity) of the condition but there were some difficulties with overdiagnosis, particularly among the more intellectually impaired. By the time of DSM-IV, 10 years of work had accumulated, and the DSM-IV definition, developed in conjunction with ICD-10, included 12 criteria grouped in three sets. This polythetic definition converged with the ICD-10. Also, in DSM-IV, Asperger disorder was first recognized, along with Rett and childhood disintegrative disorder (CDD); in the two latter groups, a marked deterioration of function was observed. For Rett’s, the potential for confusion with autism was minimal, but it was felt it needed to be included given its distinctiveness and potential for genetic association (and indeed a specific gene was found to be associated with the condition). The unusual onset of CDD (autism that appeared after some 3 to 4 years or so of normal development) appeared to deserve special recognition; the condition itself had a long history antedating that of autism. In addition, in DSM-IV, and consistent with DSM-III and III-R, a category for cases that did not achieve a specific diagnosis but whose troubles resembled those of autism was included—PDD-NOS; such cases would today be recognized as part of the BAP.

Table 43–2.
Severity Levels for Autism Spectrum Disorder

Severity Level	Social Communication	Restricted, Repetitive Behaviors
Level 3		
“Requiring very substantial support”	Severe deficits in verbal and nonverbal social communication skills cause severe impairments in functioning, very limited initiation of social interactions, and minimal response to social overtures from others. For example, a person with few words of intelligible speech who rarely initiates interaction and, when they do, makes unusual approaches to meet needs only and responds to only very direct social approaches.	Inflexibility of behavior, extreme difficulty coping with change, or other restricted/repetitive behaviors markedly interfere with functioning in all spheres. Great distress/difficulty changing focus or action.
Level 2		
“Requiring substantial support”	Marked deficits in verbal and nonverbal social communication skills; social impairments apparent even with supports in place;	Inflexibility of behavior, difficulty coping with change, or other restricted/repetitive behaviors appear frequently enough to be obvious to the casual observer and

	limited initiation of social interactions; and reduced or abnormal responses to social overtures from others. For example, a person who speaks simple sentences, whose interaction is limited to narrow special interests, and who has markedly odd nonverbal communication.	interfere with functioning in a variety of contexts. Distress and/or difficulty changing focus or action.
